ADDRESSES AND ORIGINAL ARTICLES

PSYCHOTHERAPY IN GENERAL PRACTICE*

BY R. D. GILLESPIE, M.D. GLASG., M.R.C.P. LOND., D.P.M.

PHYSICIAN AND LECTURER IN PSYCHOLOGICAL MEDICINE, GUY'S HOSPITAL

29

It is still asserted occasionally, and the curriculum in many medical schools still seems to support the assertion, that psychiatry is mainly a post-graduate subject; by which it is implied that psychiatry is a highly specialised branch of medicine, too abtruse for medical students, and rather useless in practice anyway.

The reason for this view lies probably in the fact that the statutory teaching in psychological medicine is confined to the demonstration of patients resident in mental hospitals. What a small proportion of the whole field of psychiatry is occupied by the in-patient population of mental hospitals is well shown by the statistics of a special out-patient department in a general hospital, such as the department for nervous diseases and psychological medicine at Guy's. Of approximately 600 consecutive cases, 436, or nearly three-quarters, were diagnosed as psychoneuroses, and 129, or under one-quarter, were diagnosed as psychoses, including for convenience and contrast in that category not only manic-depressive, involutional melancholic, schizophrenic and paranoid conditions, and organic reaction types, but epileptics and mental defectives as well. In other words, at an out-patient clinic designed to cater for all kinds of mental and nervous illness, the psychoneuroses were at least three times as frequent as all the other mental conditions lumped together. Further significance lies in this, that hardly any psychoneuroses are admitted to mental hospitals; hey remain as one of the sets of problems of which general practice is composed.

It would be a mistake to regard the above figures as more than a pointer towards the relative numerical mportance of psychoneuroses and psychoses. It is extremely probable that the incidence of psychoneurotic conditions among the general population s considerably greater than the figures for a special linic indicate. After all, the general practitioner ees in each year of his work only a few patients who are obviously psychotic—i.e., suffering from a mental illness of a type and severity necessitating admission o a mental hospital—and to say that he encounters sychoneurotic conditions thrice as often is not to ssert much in absolute numbers. But it is only he more obvious cases of psychoneuroses that are referred to a special department. The rest remain s out-patients in other departments of the hospital, eing regarded as part of the inevitable load of cases f the more chronic kind. One's gynæcological olleagues declare that many of their patients are uffering not from any important physical lesion, but om psychoneurotic conditions whose symptomatic xpression seems to be mainly in the gynæcological eld. The same applies to dermatology, to cardiology, nd, in fact, to medicine in general. The point is ot simply that psychoneurotic conditions occur hich masquerade as gynæcological, dermatological, rdiac, or other states of bodily ill-health, but that a numerically important proportion do so. Such statistics as can be obtained are indirect in their bearing but their meaning is unmistakable. A well-known consultant in general medicine, who sees as wide a range of conditions as most people, and who certainly does not have any prejudices in favour of psychological medicine, tells me that among the six most frequent diagnoses which he is called upon to make, "anxiety-neurosis," as he calls it, is one. I have asked many doctors in general practice what proportion of psychoneuroses they roughly estimate they encounter in their everyday work, and they have given me estimates which, for fear of seeming to overstate the case, I shall not quote.

There is another source of information, however. Everyone knows that the rise in the cost of sickness benefit, under the National Health Insurance Act, has been causing concern. Inquiries in certain industries have shown that as much as 60 per cent. of the time lost through sickness is lost through psychoneurotic illness of some kind or other (Lockhart).

It is still, I think, necessary to labour the considerable prevalence of psychoneurotic illness because older views die hard; and many, perhaps the majority, of psychoneuroses still go unrecognised under diagnosis of anæmia, gastric catarrh, debility, neurasthenia, and the like. But enough has been said to show how important it is for any doctor to be able to recognise and, if possible, to treat conditions of such frequency and of such polymorphous symptomatic appearance.

The Psychotherapist's Equipment

As for treatment, there is an impression, and it is partly true, that psychotherapy is a specialist's job. So it is, in its more technical forms. But a considerable proportion of psychoneuroses do not require a highly specialised technique. This is as well, since technical psychotherapy is essentially a prolonged affair in many instances. What is commonly described as the old type of family doctor had an insight into, and a consequent ability to treat, psychoneurotic conditions because he had a profound knowledge of human nature. But such almost unconscious psychotherapy has its limitations, and there is no reason why the general practitioner of to-day, in spite of the preoccupation of his medical education with X rays, blood tests, and other laboratory methods, should not be more successful than his predecessor of 50 years ago in treating the symptomatic results of life's difficulties, dissatisfactions, and disharmonies, in the health of his patients.

The first requirement of a psychotherapist is a good knowledge of general medicine, otherwise he is likely to involve his patients in danger and himself in ridicule. Nowhere in medicine is a knowledge of the natural history of disease of more use than in the diagnosis of psychoneurotic illness as a first step towards treatment. In psychological medicine, almost more than in any other branch, an accurate history is indispensable not only for diagnosis but, as I hope to show, for treatment. In mental illness of any kind it is still clinical observation that matters most. For the great majority of mental illnesses and especially for the psychoneuroses, serological, radiological, and other laboratory experiments are of only negative value, as excluding the possibility of organic disease. Much of the rest of the psychotherapist's equipment is already contained in the phrase "a knowledge of general medicine," because that knowledge should include something about the psychology of human nature. But this is a field in which too much knowledge is, in a sense, a dangerous thing. The tendency for the man who specialises in psychotherapy is to make his own path more and more difficult. He sees ever-widening theoretical ramifications in every case he meets, and anything short in time and thoroughness of what he considers the ideal is stultified by his own lack of confidence in it. The tendency is for some of us to become increasingly ineffective in the use of shorter methods, and to look back regretfully to the days of our psychotherapeutic adolescence, when we would produce not cures, perhaps, but dramatic improvements in a minimum of time. The preface to T. A. Ross's book on "The Common Neuroses" gives a good account of a progress of the kind. There is another danger, too, that a wide theoretical knowledge applied without a critical and careful discrimination, based on extensive experience, can do a psychoneurotic patient harm which it is very hard to repair.

---

* A lecture delivered before the Leeds Medical Society.

What knowledge, then, of psychology should the general practitioner have? He should have a sympathetic acquaintance with what is called human nature, which means its envyings, jealousies, rivalries, as well as its affections. He should have also an appreciation of the power of conflicts arising in relation to such tendencies to produce bodily disturbances. In other words, he should have an appreciation, based on experience, of how psychological factors can cause what looks like "disease." I propose to specify the kind of knowledge I mean, first by giving some indication of the kinds of symptoms that are in practice most commonly produced by psychological factors, and then by describing some actual examples of typical psychological conflicts and their resolution by simple methods of psychotherapy.

Classification

Psychopathologists are often accused of being too academic. I will therefore try to make this address as practical as may be, and for that purpose will make the most ordinary subdivision possible of the disorders that constitute our subject matter.

The subdivision is into the definitely curable and the merely manageable. By "curable" I mean capable of active treatment, immediately following upon which the symptoms disappear; by "manageable" I mean lending itself only to symptomatic treatment and recovering, if it does recover, only with the passage of time, however much one may flatter oneself about one's own share in the matter. Of course, such a division is completely unscientific. In therapeutics one man's meat is another man's poison; what some of us would rejoice to treat, others should avoid like the plague; this is true of psychotherapy if not of other branches of medical treatment. But in psychotherapeutics it is certain patients, not certain diseases, that are specially apt for treatment by some doctors and not by others. It is a matter of personalities and of particular types of personal as well as clinical experience.

If I am to give a list of the functional nervous conditions falling into the curable group, it is with the understanding that they are to be regarded as types specially susceptible to cure, and that individual instances may not prove curable at anyone's hands. The curable disorders include many cases included in the following purely symptomatic categories.

1. *Nervous exhaustion*, in which, in addition to feeling exhausted, the patient often complains of brain fag, poor memory, excessive fatigue, irritability, or insomnia.

2. The *anxiety group*, in which the complaints are of headache (of the type of "pains in the head" or "a constricting band"), giddiness, palpitation, præcordial pains, insomnia, indigestion (pains in the stomach not specially related to meals), tremulousness, polyuria, &c.

3. Instances of the so-called *vasovagal attacks* which are often a variety of the previous group. (Some vasovagal attacks, of course, are not of psychological origin.)

4. *Hysteria* of the "conversion" type: weakness, paralysis, or tremor of limbs, fancy gaits, aphonia, anæsthesia of special senses, loss of memory, and fugues.

5. A very common type: *depression of spirits.* These are frequently varieties of group 2.

6. Certain *morbid fears*, especially of illness and usually a part of group 2. Other morbid fears (phobias) such as fears of open or closed spaces, fear of animals, of going out alone, cannot so readily be placed in this class. Many of them are curable—all of them theoretically so—but many of them only by technical and prolonged methods of psychotherapy. This is especially true of those morbid fears which form part of the symptom-picture of obsessive compulsive psychoneuroses. Only a minor proportion of the latter are susceptible of cure, even by prolonged analytic psychotherapy.

Compensation neuroses, although usually having the form of an anxiety state or of hysteria, belong, as a rule, to the manageable and not to the curable class. I shall not refer further to the other merely manageable types in general; for the most part they are what one usually designates as psychoses, although I do not want it to be inferred that no psychosis is susceptible of psychotherapy.

Physical Examination

There are some general principles which apply to all the types. An essential preliminary is a careful physical examination. This is not entirely for one's own satisfaction; it helps to establish the patient's confidence. Frequently these nervous patients have been dismissed with a rather cursory examination in the past, they are obviously healthy physically; they have often cried "Wolf," and now it is assumed to be the same again. Even if they have frequently been examined by others to one's own knowledge, I believe that it is very desirable when consulted by such a patient to make a physical examination. A very large number of them fear that they have some physical disease. Modern psychotherapy is largely a talking cure, but few such patients believe much that is said to them by a doctor who has never examined them. If a physical lesion is discovered it is necessary to consider its relevance to the complaints.

The fallacy of irrelevant pathology.—Even definite septic foci, pace the bacteriologists, have not necessarily a causal relation to the symptoms. I have met a patient who had tonsillectomy, mastoidectomy, appendicectomy, cholecystectomy, and myomectomy, and still retained her symptoms which were typically neurotic. I have met another who, in the early days of this operation, had a gastro-enterotomy for a "dropped stomach," the symptoms referred to which depended largely on her father's bad temper. "Better a dinner of herbs where love is, than a stalled ox and hatred therewith." Another unmarried woman had all her teeth out because, if her doctor had only known it, she was unhappy at home; while the loss of her teeth made it all the more likely that she would have to remain there.

The fallacy of phantastic pathology.—Neurotic symptoms have, until recent times, been so mysterious that when no organic lesion has been discovered, the natural tendency has been to suppose that there must be a lesion somewhere if one were only clever enough, or one's instruments refined enough, to discover it. There was, for example, the eyestrain hypothesis. It is interesting to note that at a meeting of ophthalmologists, reported in the *British*

Medical Journal about two years ago, it had been discovered that errors of + or − 1 D. do not cause nervous exhaustion, and that the correct treatment was not glasses but common-sense guidance of the patient's life, which "did not require the coöperation of a psychopathologist," whereby they spurned those who had taught them wisdom. But the commonest diagnoses of this kind are still anæmia, gastric catarrh, influenza, and auto-intoxication—anæmia for any vague symptoms whatever; gastric catarrh for symptoms referred to the digestive functions; and influenza for symptoms of more acute onset, especially malaise, weakness, and trembling. When influenza is mentioned in the history I have learned to examine the details carefully; often there has been no pyrexia, and the only diagnosis has been the patient's own. The same applies to any other diagnosis, and indeed to any other statement proffered by the patient. One of the things I have learned is never to take, without further inquiry, anything a psychoneurotic patient says about important events in his history at its face value.

Fallacies of omission.—Errors in diagnosis of the kind described arise from the simple facts that the examination has been incomplete, and that the copious influence of mental factors in producing symptoms has not been considered. As students we received from our medical curriculum a strong bias in favour of a physical ætiology for everything. Things are changing now, but until very recent years it was uncommon for students to be taught that præcordial pain, breathlessness, and the like, could result from mental conflict, or that hysteria was anything but the weird perversity of the congenitally queer. The result is that our investigations have usually been incomplete, no matter how thorough the physical examination may have been, because the psychological aspect has been persistently overlooked. In 99 cases out of 100 in which no adequate physical lesion has been found it is correct to assume a psychological cause. It impressed me considerably after acquiring the physical bias imparted by my clinical teachers, who were unceasingly modernising themselves, as they quite rightly thought, by basing their teaching more and more upon physiology, to find on working in a physiological laboratory as a post-graduate that the physiologists themselves were acutely conscious of what they called the psychological factor. These attitudes of the clinicians to the physiologists and of the physiologists to psychology remind me of Bertrand Russell's remark about the physicists and the biologists. The biologists, he says, turn for the consolation of ultimate explanations to the physicists, while the physicists of late years turn only to God.

Psychological Examination

A clinical examination can include the psychological aspect of a man without much extra trouble. There are two kinds of psychological examination which might well be called the cross-sectional and the longitudinal. The first is directed simply to eliciting the presence of symptoms which are psychological and is principally of diagnostic value. The simple query "Are you worried?" may often give a chance for most useful information to appear. There is a short form of inquiry which we use on those lines as a routine at out-patients at Guy's, and which usually prevents one missing, even in the hurried work of an out-patient department, the essential manifestation of nervous or mental illness. Neglect of even this shortened survey can lead to serious errors. I have seen a hospital report on a case of general paralysis of the insane in which the mental aspect was dismissed with the comment "mentality normal." Fortunately, in general paralysis some very definite physical signs ordinarily come to the rescue. But in the psychoneuroses they are not there to do so.

One of the commonest experiences is to find a patient who has had several abdominal operations for certain symptoms referred to the alimentary tract, although there has been no definite signs, and who is no better, but rather worse after the operation than before. In many instances the operation would have been avoided if such a brief cross-sectional mental examination had been made as I have indicated. Not long ago I saw a man who had undergone an exploratory laparotomy for certain symptoms in his abdomen. It had not been observed that he was depressed and anxious, and that eighteen months previously he had been in a mental hospital where he had complained of the same symptoms which had disappeared with a temporary remission in his mental state. A still more striking instance of this sort came to my notice some years ago of a patient who had had an exploratory craniotomy.

His complaint was that he had frequent headaches, and that his left hand went into spasms at irregular intervals. A careful neurological examination revealed what was believed to be a spasm of the right sternomastoid and a slight left facial weakness. On the basis of these admittedly slight signs a meningioma was diagnosed, and on the strength of this neurological opinion the surgeon, very reluctantly and doubtfully, operated. He did not find the meningioma that had been diagnosed, which did not surprise him. The skull-flap was closed, and because some thickening of the arachnoid had been noted the house surgeon wrote up on the patient's bed-letter the diagnosis, "chronic meningitis." Subsequently it was discovered that the patient was going round public libraries consulting encyclopædia articles on meningitis. This prompted new inquiries, and it was found that the patient had been depressed and worried before the operation, that for years he had been discontented with his job, and that at home he was cantankerous. In brief, the clinical signs of a mental condition were so much more positive than those of any physical disease, that the greater probability lay in a diagnosis of an anxiety state than of a meningitis. The subsequent history, extending over three years, has proved the accuracy of this opinion.

The cross-sectional clinical examination of the psychological factors is, however, of mainly diagnostic value; for treatment the longitudinal method, in other words, the taking of a history of the patient as well as the history of his symptoms is essential. The cases which I shall quote will illustrate in some degree the use of the longitudinal method.

I should add also that care in eliciting symptoms of a psychological type, and in taking an accurate history, is not a sufficient prelude to successful treatment. It is also necessary to have sound views on psychopathology, and to have at least an appreciation that the symptoms can be produced by purely psychological causes. This avoids such catastrophes as one I saw recently. A woman in the late 'thirties had complained of various paræsthesia, trembling, and other symptoms which together were correctly enough labelled "neurasthenia." But the treatment prescribed for the neurasthenia was hysterectomy, and a perfectly sound uterus was removed, with the usual result in such circumstances that the patient remained as ill as before and certainly with less prospect of recovery. Such a history-taking should ordinarily precede a physical examination, but in practice it would save time in some instances if it followed the physical survey. If we assume that nothing physically abnormal has been found, or if found does not seem to be relevant, the next stage in treatment is to obtain the type of history I have mentioned, and to see if one can correlate the development of the symptoms with the patient's own account of himself and of his circumstances.

Nervous Exhaustion

Patients of the first group, those complaining of exhaustion, furnish some of the simplest examples of this method. It happens that I have encountered a patient whose story singularly well exhibits the characteristics of exhaustion or "neurasthenia" not dependent on physical disease, and who also illustrated, in the history of his treatment, most of the theories that have been held on the ætiology of typical neurasthenia or "nervous exhaustion" in the past 30 years.

He was an army officer who, while serving in the East during the last year of the last century, suddenly complained of malaise, was diagnosed as suffering from malaria, and took to his bed.

During convalescence, from what appears to have been a mild attack, he found that his legs were very weak. The weakness persisted to such an extent that even after some months he was unable to return to duty. "Nervous exhaustion" was diagnosed, and he was ordered a complete rest on Weir-Mitchell lines, after which it was found that though he had more use of his legs he was readily fatigued. On some occasions he bicycled 20 miles, but always suffered terribly afterwards and had to remain in bed, exhausted, for several days. He consulted an eminent authority of the time, who said that he had "spinal neurasthenia," and added that neurasthenics differed entirely from hysterics in that they always tried to conceal a real disability while hysterics made the most of an imaginary one. Following this the patient spent some years in and out of nursing homes for periods of rest, which would serve for a time, but always the fatigue returned.

The next outstanding episode in treatment followed a new diagnosis of endocrine, and especially adrenal, insufficiency. He now received injections of adrenaline, especially before making any unusual effort which he felt inclined to make in a social way. After a time these injections lost their stimulating effect, and various other endocrine preparations were tried in turn, without however even temporary effects this time. It was then suggested that the postulated endocrine deficiency was secondary to an intoxication of intestinal origin. The stools were cultured accordingly, an organism isolated, a vaccine made and injected, and the bowel irrigated. Again there was a temporary effect. In 1925 focal infection was suggested, and his teeth were removed practically wholesale with no lasting result.

In 1927, when he came under my observation, the weakness and fatigue were worse than ever, and he could hardly walk across his bedroom. It was now nearly 30 years since he began to suffer from his neurasthenia. He had done no work in his profession during that time, having, in fact, resigned long ago, but he had taken up a part-time job which he conducted from bed. Organically he was sound, and in fact very well preserved for a man of 60. Investigation of his mental attitude revealed a very unhappy man who had loathed his profession from the beginning; even his Sandhurst days had been a misery to him.

The treatment here consisted in :—

1. A careful physical examination.

2. A systematic and chronologically detailed history of the symptoms in relation to the patient's personal history, career, and so on.

3. An explanation to the patient that (*a*) he had no physical disease, but (*b*) that his symptoms, however, were not nothing; that they were real and must have some definite cause.

4. An explanation of the effects of the emotions on the viscera, especially in producing fatigue. Everyone knows that worry, to take the commonest example of an emotional state, is extremely fatiguing, and I know no two symptoms that go oftener together than fatigue and depression of spirits.

5. The effect of false inference—i.e., that the fatigue was due to bodily disease and not therefore avoidable by him—in perpetuating his symptoms and in making him expect to feel tired, was pointed out.

6. He was then encouraged to increase his activity not gingerly by inches, but by leaps and bounds. As there was nothing physically wrong with him, and only his own misconception and discouragement based on this prevented him from being perfectly normal, he could walk as far as he pleased. And this he did, after 30 years of semi-invalidism. For the next five years he remained active, and then for a time relapsed, but not with his former symptoms. This time he was mainly depressed about his life and circumstances, as indeed he had reason to be.

This sounds a long process but it can really be quite short. I have known it to be compressed into a single interview of little more than an hour, even in a condition of as long duration as the one I have mentioned.

A particular instance in a man of science showed well how a particular emotional experience, if its effects are misunderstood at the time, can produce a chronic psychoneurotic symptom very resistive to ordinary treatment.

This was a man of middle-age who complained of "brain-fag," which took the form of inability to read for more than about 40 minutes at a time. He then had to rest for half an hour befor he could resume. This had handicapped him considerably in his work for examinations which had been essential to his scientific career. We investigated the history of the symptom in a straightforward, chronological way. It had first appeared 30 years or more ago, when the patient was about 13. At that time he was taking some of his work in classes from the headmaster of his school, whom he disliked very much. The headmaster remarked to his mother that the boy had an under-developed brain, and the mother had injudiciously communicated this to the boy. The latter, although doing well in his other subjects, believed this, and noted anxiously that he gained weight in the summer and lost it in the winter. He concluded that this was the result of overstrain of his "under-developed brain," and so he became afraid to read for more than a certain period of time. In his fear he automatically assumed that he would become fatigued after this period, and it had become a habitual fear producing the effect long after the reason for it had been forgotten.

When he remembered all this, as he succeeded in doing after an hour and a quarter's effort by the patient and myself, he naturally asked what was to be done now? What he had ventilated had surprised him a good deal—so much so that I felt it was a "true bill," and advised him to proceed forthwith to the nearest technical library and read there for at least two hours. This was on Friday. I asked him to return to me on the Monday. He appeared looking rather sheepish, and admitted that he had now no difficulty in working for as long as he pleased. The therapeutic process here was simple enough. It insisted on an accurate chronological history of the development of the symptoms; a physical examination, an assurance based on the latter that a physical cause was out of the question, and then an inquiry into the history of his life as distinct from the history of his symptoms, but focusing especially round the time of their remembered origin. The entire process took an hour and a quarter, and cleared up a symptom which had troubled him for 30 years. This would have been impossible if the patient had not been highly intelligent and keen to get well.

The key to the successful treatment of a case of nervous exhaustion is not to tell the patient that he has nothing the matter with him, which is palpably false; but to explain how emotional factors can cause fatigue, and then to demonstrate their existence in his own case. In exhaustion of this kind rest has no place in therapy; it is, in fact, contra-indicated as definitely harmful. But there are certain cases of exhaustion without existing physical lesion and with symptoms similar to those of the sort described, such as insomnia, irritability of temper, hypersensitiveness to noise, and the like. This is the "hyperæsthetic-emotional state of weakness" of German authors, and is distinguished from the former principally by the history, which contains real and definite overwork, or such causes of severe physical debility as parturition or acute infection. That the overwork has been real it is important to establish, for many a neurasthenic pleads overwork as an honourable occasion for his breakdown; but real overwork means something of the nature of sewing shirts until 10 P.M.

every day and on Saturdays and Sundays as well, as in the case of an out-patient seen at Guy's recently. In the instance of another woman, also an out-patient, it meant nursing four children through an infectious illness, bearing a fifth in the space of the same few months, doing all the housework, and sleeping little.

The symptoms in both these cases were difficult to distinguish from neurasthenia of emotional origin. They did, in fact, result partly from an anxiety based on the fear of incapacity for work and responsibilities. Nevertheless, even in patients with a history of recent physical stress, it is wise if they present symptoms with an ambiguous look to inquire into the more personal aspect of their lives. I recently felt fairly sure with a woman patient that she was suffering from a "hyperæsthetic-emotional" type of disturbance resulting from real overwork in her home and with her ailing children, until I discovered that she was all the time miserably unhappy with a drunken husband.

There is another possibility of error here. A history of an acute illness is by no means decisively in favour of an ætiology of a fatigue syndrome that is principally physical. Sometimes the post-febrile weakness and debility perpetuate themselves as suggestions of weakness. The convalescent patient does not always realise that he has fully recovered.

For example, I remember a pioneer airman who, crashing badly, retired permanently from flying but recovered his health completely. The retirement, however, left him with nothing particular to do. Several years later, in 1923, he had an influenzal pneumonia from which he ultimately recovered, only to find even after a year's convalescence that he could only take a very limited amount of exercise This limitation persisted for about four years until I examined him in 1928. I found a very healthy and well-developed man, and told him so. He replied that it was very odd that he could walk no further than 300 yards without extreme fatigue. I removed him temporarily from his wife, who was a little older and mothered him too much. I encouraged him to believe that he was physically quite well, and that he could do anything he wanted to if he would only believe it. It took three weeks to convince him of this, but at the end of that time he was living a natural life, playing all the games, such as golf and tennis, that he formerly enjoyed, and taking part in amateur theatricals.

Here again the treatment and its success depends on an accurate analysis of the history, not only of the disease, but also of the personal circumstances; and especially, in this particular case, of the temperament, which was an over-anxious one. I believe that an accurate history, coupled with an ordinary but complete clinical examination, is of far more value in the diagnosis of disease in general, and consequently in treatment, than test-meals, X rays, measurements of blood pressure, or bacteriological examinations taken singly or together, and there are many clinicians in other branches of medicine who agree with me. Alvarez's recent book on nervous indigestion comes to the same conclusion, and Alvarez is a physiologist and a clinician. It is not that laboratory methods do not have their value, even in the treatment of psychoneurotics. There is nothing more convincing, in a superficial way, to some of them, than a negative radiogram. Not the most vehement assurances of the most impressive doctor carry more weight than that. But X ray photographs are expensive methods of reassurance, and they serve at best only to lessen preoccupation with a particular symptom.

Anxiety Neuroses

The second and by far the largest group of so-called functional nervous conditions is the one usually designated, not very accurately, as an anxiety neurosis or, more accurately, a psychoneurotic anxiety-state, and by Freud as anxiety-hysteria. It must be one of the commonest conditions seen by any doctor, and it has a multitude of symptoms. Usually, many of these symptoms are gathered together in one patient. They may implicate any or all of the bodily systems, but usually the patient tenders only one or two. The rest can usually be elicited by questioning him, and the fact that symptoms are found to exist with regard to practically every system in the body, is almost diagnostic of the condition, although not a necessary mark of it. The complaints are uniform enough from patient to patient to enable some of them to be regarded as typical; and they have sufficient resemblance to the effects of bodily disease to give rise to a frequent possibility of error. In the cardiovascular system they usually include palpitation and præcordial pain; in the respiratory system shortness of breath usually, less often cough, or difficulty in getting a breath, sometimes mistakenly described as "asthma"; in the nervous system, headaches in the form of pain in the head or a band round the head, tremblings, insomnia, fatigue, nightmares, and paræsthesia such as numbness or pins and needles; in the digestive system fullness in the stomach, flatulence, vague pains in the abdomen, vomiting. and diarrhœa; in the genito-urinary system, frequency of micturition or inability to micturate under certain circumstances, dyspareunia, spermatorrhœa, and premature ejaculation.

The differential diagnosis from organic disease is sometimes difficult. In the absence of any very definite physical signs one should always think of the statistical probability of a psychological origin for such symptoms as those above mentioned. The history is the main thing, both from the diagnosis and as a basis for treatment. A knowledge of the natural history of clear-cut organic disease is invaluable, and usually the history of the symptoms in the anxiety states is very different from that of the organic diseases they suggest. If the symptoms are cardiac. then the dyspnœa arises as much apart from exertion as with it, even at rest or in the middle of the night, and præcordial pain is common and persistent. If the symptoms have an alimentary reference actual pain does not occur, or if it does, has no relation to food and is indefinitely localised as a rule and changes its position frequently.

For example, a man of 47 complained of pain when he awoke in the morning, and discomfort when he went down to breakfast which was completely relieved while at breakfast, but was replaced by pain again after half an hour's rest after breakfast. This was followed by relief till lunch, after which "the real thing" began and lasted till bedtime. This is not like the history of pain belonging to any of the organic diseases of the stomach.

The mental attitude is one of anxiety but the patient may not mention this. He fears that there is something the matter and usually something serious. The fear most commonly present, and one that he mentions last if he does put it into words at all, is the fear of insanity.

Everyone knows that an examination and reassurance that there is nothing wrong is sometimes all the treatment that these patients require; but frequently after this process they relapse or go elsewhere. Sometimes they go away. discontented from the beginning with the assertion that it is nothing. Obviously there must be something, they think, or they would not have symptoms like these. They are quite right. They have something only it is not what they surmise. The next step after a negative physical examination is to give an explanation why the symptoms nevertheless exist. It has to be explained what the general public brought.

up on a purely physical conception of disease does not realise; that one's thoughts and feelings can affect the functions of one's viscera. People learn in a general way that fear makes one's knees tremble, but they do not realise how readily fear can make one's heart beat more forcibly and one's peristalsis cease or actually reverse itself. It is easy enough to give them chapter and verse for these facts, and it is best to choose as vivid and impressive instances as possible, proceeding, however, from simple examples such as the fear and knee-weakness sequence. One of the most telling I find is the story of the experiment in which a window is made in a cat's abdomen and then after the anæsthetic has been recovered from, a dog is exhibited to the cat. Peristalsis ceases absolutely. Examples from real life are common enough. The effect on the lower bowel on going over the top in the late war was well known. For more squeamish patients examples are most easily found in the literature of antiquity. Joseph's bowels yearned upon his brother Benjamin, and in the first epistle of John the "bowels of compassion were shut up." Sennacherib thus describes his battle with the two kings of Elam: "The vehemence of my battle line like a bull overwhelmed them. To save their lives they trampled over the bodies of their soldiers as they fled. Like young captured birds they lost courage. With their urine they defiled their chariots and let fall their excrements" (quoted by Cannon). The *Dulce et decorum* ode contains a reference to the *poplitibus trementibus* of the less ardent youths. The common phrases "a heavy heart," "cold feet," and a "lump in the throat" all are founded on the observation of definite psycho-physiological occurrences.

There are quotations and instances to suit all tastes. The physiological and clinical literature has many examples, ranging from the increase in the reducing power of the urine in a diabetic who has become worried, to the change in the loudness of the bruit in a cavernoma angioma within the cranium when the patient thinks hard. I had a young woman patient who vomited every time a young man made love to her, and who nearly died of acidosis during her engagement. Alvarez gives some good examples:—

> "When I was studying the intestinal movements of a man with an opening through the abdominal wall into the first portion of the small bowel, a small balloon connected by rubber tubing to a tambour was passed into the bowel and with it I was able to record every movement that took place. As I sat by the bedside watching, I noticed a sudden rise in the level of the tracing and an increase in the amplitude of the contractions and looking about for some cause I heard the rumble of the steam table as it came down the hall bearing the patient's luncheon. He was hungry and had heard it first. This sudden increase in the activity of the bowel coincident with the arrival of luncheon was observed on two occasions.
>
> "The most striking evidence of a psychic increase in tone and activity was seen in a jolly *bon vivant* whose anal sphincters had been destroyed by a series of operations for fistulas. As a result many of the rush waves down the bowel, instead of stopping, as they normally do at the ileocæcal sphincter or somewhere in the colon, ran on and produced a bowel movement. The interesting point is that in this man the sight and smell and even thought of food produced rushes. They were most annoying at breakfast-time, when after the night's rest the bowel was most sensitive, and as a result he had to eat his breakfast in the bathroom. Ordinarily, except for meal-times, he had little difficulty unless, perhaps, when passing a restaurant he happened to catch an appetising whiff of food, or unless some practical joker among his cronies, knowing his infirmity, began to discuss before him the relative merits of Hungarian goulash and beefsteak and onions. He knew the site of every restaurant in town and never went near one if he could help it."

Sometimes a general explanation along these lines is sufficient to send the patient away permanently satisfied. Very much more often it is necessary to find both particular and general cause of the constitutional upset, and this may be, but is not necessarily a prolonged business.

For example, a certain patient was described as "a queer mixture of shrewdness and ability and of stupidity over symptoms." He complained of indigestion which began in 1920; he was operated on for appendicitis, and afterwards tubercle was diagnosed. He was treated successfully in a sanatorium, and was warned that if he ever allowed his stomach to get out of order it would give an opening for tubercle to flare up. A diet was recommended, he stuck to it, remaining well till his wife fell ill in 1927 and underwent an operation. A week after this he developed a severe abdominal pain of a type that had no relation to meals and was very curious in its time incidence. He was given a long interview, the significance of the commencement of his symptoms at a time of emotional stress was explained to him, and the part played by his anxious temperament and the impression made on him by previous diseases was made clear. He departed apparently satisfied; at any rate, his doctor reported that he never complained again.

The short procedure is to get a history of the development of the symptoms and to focus one's attention round the time of their origin. In most cases it is possible to find factors of a distinctly personal and emotional nature by diligent search, operating at the time of the outbreak of the symptoms. Often it is a matter of the climax of troubles which have been accumulating for some time, but the things that determine the actual outbreak of symptoms at that particular moment is sometimes apparently trivial.

A young woman with attacks of trembling, palpitation, and dizziness, related that they first occurred six weeks previously. She denied a special worry at that time. On going into details we found that she had the first attack while watching a moving picture. She was accompanied at the time by a girl friend with whom she was on perfectly ordinary terms. Nothing had occurred that day to disturb her. Questioned as to the subject of the moving picture, however, she mentioned that at the moment she fainted the heroine on the screen was contemplating suicide. Only then did it emerge that the patient herself had had similar thoughts recently, and this led to an admission of what she had previously refrained from talking about—namely, the presence of a personal conflict revolving round a disappointment in love.

Not only does the discovery of a personal association of this sort give point to one's general explanations to the patient; it leads to the transfer of the patient's interest from the symptoms to the personal difficulties underlying them. The treatment then ceases to be symptomatic and gets down to causes. For this reason, although one has to treat many neurotics with symptoms in many systems—e.g., in the digestive system—one seldom has to treat the symptoms as such. It is neither necessary nor wise to prescribe bismuth or HCl or whatnot in the absence of definite physical indications. There are certain general lines of search that are useful in patients who have to be treated rapidly.

They are in the case of adults: Financial affairs, relationships at work (attitude of employer and fellow employees, rates of pay, chances of promotion, liking for work), domestic affairs (relationships to husband or wife or others, especially parents living in the same house), marital difficulties (temperament as well as actual sex relationships), attitude about children, the question of further pregnancies, unwanted pregnancies, &c. The domestic problems are the most important but professional and business relationships, especially the suitability of a job and chances of promotion, play a larger part than is generally realised. In young unmarried people one asks about the attitude of parents, brothers, and sisters, the hours of work, the choice of a career, type of recreation, and if it seems necessary, the attitude to marriage and to sex itself. Systematic inquiry along these lines can rapidly be pursued with hopeful results if the replies are carefully watched and the manner of giving them, especially negative replies, carefully scrutinised. Often a slight change of expression will denote to the practised observer a hedging on some of the topics touched upon.

"Vasovagal Attacks"

There is a subvariety of anxiety attacks called "vasovagal." There is as much scientific justification for supposing them to constitute a nosological entity as there is for setting apart tachycardia as a disease. The suggestion has been made that vasovagal attacks are a form of epilepsy and some such attacks doubtless are, but in many there is a good deal of objection to classifying them with epilepsy. The vasovagal syndrome is simply a pattern of reaction which may be touched off by a variety of factors from a domestic fracas to a neoplasm of the medulla. The central features of these attacks are a general disturbance of a type suggesting vagal stimulation and a subjective sense of impending death. A sense of constriction in the chest, cardiac inhibition sometimes to the extent of syncope and abdominal pain, are among the principal symptoms in addition to the "angor animi."

The disappearance of these symptoms following simple psychotherapy is sometimes astonishing.

There was some time ago a woman admitted to Guy's with a history of two years' duration of such attacks. She experienced a paræsthesia or numbness involving the left side of the mouth accompanied by a feeling of difficulty in breathing, præcordial pain, and abdominal discomfort with diarrhœa. The "angor animi" was marked. In addition it was stated by her family that her lips went blue during an attack. She was a young married woman without children, and had in consequence of her attacks been advised that she must not have any. It soon became evident that she was very depressed and a few further questions elicited the fact that she was very fond of children, that she was alone most of the day, and that her husband while amiable was a quiet sort of person. On going into the history of the symptoms it appeared that they had begun suddenly while she was on her honeymoon, on the third day of it precisely. It is often unwise to broach such subjects at a first interview, but in this case it did not prove difficult to discover that the honeymoon had been unsatisfactory; there had been attempts at coitus, but for some reason they had not succeeded by the third day and it was on that day during a further attempt and failure that the first attack occurred. The situation and attacks persisted, and a doctor had been consulted who advised that she was unfit to have children and must remain so for at least two years. I wrote to her doctor and asked him to explain to her that the symptoms had originally been provoked by anxiety and frustration and perpetuated by misunderstanding, and that as far as the symptoms were concerned she could have children as soon as she pleased, in fact, the sooner the better. She recovered immediately—she never had another attack. The whole story had been elicited in half an hour.

It cannot be too much emphasised that such rapid results, I would call them as a rule considerable improvements, rather than recoveries, are uncommon; but the fact that they can be achieved at all after so many years suggests, although it does not prove, that earlier treatment such as the general practitioner has the opportunity of giving, may be effective in a much larger proportion of cases than this.

I give these as examples of what anyone with a systematic procedure and some determination can do in treating the commonest types of nervous conditions in general practice without necessarily having to expend a great deal of time. The latter is often necessary, however, in the chronic psychoneurotic whose history of symptoms dates back many years in those with phobias of trains, buses, closed or open spaces, &c., and in many of the depressed type. The simple rules I have given serve, however, for the brief type of treatment.

Hysteria

The treatment of hysterics is along similar lines as regards preliminaries, but gross hysterical disabilities, like paralysis or blindness, allow aggressive methods of actual treatment, as A. F. Hurst has shown. A hysterically paralysed limb is as a rule a very satisfactory object for the psychotherapist; although I have known some that remained paralysed in spite of his best efforts. But a disability of this sort is a far more tangible affair than is usually encountered in psychological medicine which is so full of impalpables. One can make the symptoms change and let the patient see it change in an objective way. This enables a much more rapidly convincing method of persuasion to be employed than is possible with the psychoneurotic anxiety states. An example will make my meaning clearer.

A girl of 20, who had been a stage dancer, was referred to me by my surgical colleague, Mr. W. H. Ogilvie, who had diagnosed a hysterical hip. Six years previously she had slipped and fallen during a performance, and after that had complained of pain in her knees and subsequently in her hip. She had not walked since that time and had received many treatments. She had had a semilunar cartilage in both knees excised, but latterly at least the condition had been considered tuberculous, and she had her hip immobilised at various times in extension or plaster or splints. Ultimately when she came under Mr. Ogilvie's notice and mine she was wearing a patten on the foot of the affected limb, and walked with the aid of a heavy stick. Her left leg seemed on casual inspection to be shortened, and she leaned heavily over on the same side while standing. When walking she lurched violently over on her left side and held her left knee stiff. She complained of pain in the left hip especially, but also in the right hip and both knees. In the recumbent position no deformity or wasting was noticeable and no shortening.

The treatment consisted first in explaining to the patient that there was no physical disease, that she would walk normally if she could get back her confidence in doing so, and that we would teach her how it could be done. The second part of the treatment could be described, if one wishes categorical terms, as persuasion and re-education. It consisted actually in having the patient walk up and down until she was walking practically normally. This took two hours and a half but it was worth the effort, and she emerged cured of her disability. My house physician and myself took it in relays to go on persuading her that she could walk normally and in getting her to do so.

Of course such treatment cures only the symptom. It does not necessarily cure the disease. But in a number of hysterics cure of the symptom is nearly all that is required, and at least to have begun by curing such a disabling symptom gives the therapist a valuable jumping-off ground for the rest of the treatment, which in some cases necessarily includes a prolonged and very technical form of psychotherapy. With the patient just described, the rest of the treatment was simple and not highly technical. It involved re-educating the family to a belief that the patient was really fit so that they might cease fussing about her; in helping the patient to an occupation in life—her business in life during the past six years having been the haunting of hospitals—and in helping her to a more grown-up, less child-like attitude than she had yet attained.

The methods of psychotherapy I have described require no special apparatus, but they require perseverance and accurate investigation and a willingness to spend a reasonable time soon after the patient first presents himself. By these means much time may be saved the practitioner in the long run; he himself will gain much credit, and the patient be saved much misery, grievance, and loss of time.

THE MODERN CONCEPTION OF NEPHRITIS,

AND ITS BEARING ON CERTAIN PROBLEMS OF LIFE ASSURANCE *

By T. Izod Bennett, M.D., F.R.C.P. Lond.

PHYSICIAN WITH CHARGE OF OUT-PATIENTS, MIDDLESEX HOSPITAL, AND PHYSICIAN TO THE ROYAL NATIONAL ORTHOPÆDIC HOSPITAL

All those who have been engaged in the active practice of medicine during the last 20 or 30 years must agree that there has been an astonishing change in the precision with which a diagnosis can usually be established. However much one may reverence the experience and clinical instinct of the great physicians of the last century and the epoch immediately preceding the war, it would be foolish to pretend that they were capable of identifying and classifying disease in a manner in any way approaching what is possible to-day. If we reflect on what would happen during a teaching round in a medical ward before the war, we remember most brilliant teachers arriving at conclusions which were often accurate as regards the broad nature of the disease, and not infrequently genuinely precise when the post-mortem room revealed the ultimate details, but the contrast between this and a visit to the wards of a modern hospital is really very great. To-day you will go to such a ward and see, for example, a series of cases of this description—an ulcer on the lesser curvature of the duodenal cap, a case of pernicious anæmia, with the blood nearly restored to normal but with subacute combined degeneration of the cord, a case of pulmonary tuberculosis with the disease confined to the right apex, a case of sacro-iliac strain, a case of carcinoma of the fundus of the stomach, a case of tetany due to chronic steatorrhœa, a case of hypertensive cardiac failure with auricular fibrillation, a case of dysphagia due to achalasia of the cardia, a case of diverticulitis with recurrent pain and pyrexia. These are everyday cases, and the point which I wish to emphasise is that you will find precise diagnosis established in every one of them to-day, whereas 15 years ago this was not possible, at any rate as a rule.

I do not wish to imply that this is entirely due to laboratory methods and the help of X ray examination; it is very largely due to these things, but actually precision is often reached to-day through the more exact knowledge which experience, gained by the help of these ancillary services, has given us.

Knowledge of Nephritis

When we come to nephritis it must at once be admitted that there are, in spite of the brilliant work of a host of investigators, enormous gaps in our knowledge which prevent us from achieving that precision which exists with regard to many other common diseases. Anyone accustomed to survey the world's literature dealing with nephritis is aware of considerable divergence of opinion, sometimes between country and country, and even more often between different authorities in the same country. At the same time, I would suggest to you that the last five years have seen the emergence, in many different countries, of an important agreement concerning the major aspects of nephritis amongst a body of workers who have studied the subject deeply, sometimes in collaboration, sometimes independently. These workers, amongst whom I would include Fishberg, van Slyke, Epstein, and Addis in the United States, Achard in France, Volhard and Fahr in Germany, Snapper in Holland, and Gainsborough and others in this country, are steadily reaching close agreement as to the classification of nephritis, both as regards its clinical course, its ætiology, its morbid anatomy, and its biochemical manifestations, and although I think not one of them would suggest that anything approaching finality has been reached, they nevertheless represent an agreed conception concerning the general features of nephritis which is something quite new in the long history of medical inquiry into this subject.

I cannot put before you more than a somewhat fragmentary outline of the major points in this conception, but some of these will, I think, be of value in deciding when, and in what manner, a person with a history of nephritis, or with evidences pointing to nephritis, can be accepted by the examiner for life insurance.

Renal Failure

The first conception to which I would draw attention is that of "renal failure." By this we mean a condition in which so great a proportion of the total kidney substance is temporarily or permanently out of action that the physiology of the body is deranged.

The normal kidney is made up of a vast number of individual units, each of which begins in a glomerulus; nature has provided far more of these units than are essential for life; it is a common observation that half the total kidney substance—i.e., one of the two kidneys—may be lost without permanent impairment to health, and we know that actually between two-thirds or three-fifths of the total kidney substance must be out of action before renal failure is established. A useful analogy may be drawn between renal failure and cardiac failure; each of these conditions may be temporary or permanent, and each of them may be compensated or decompensated. Just as toxæmia may produce acute cardiac failure from which the patient ultimately recovers, so an acute nephritis may produce a condition of renal failure which is not by any means necessarily permanent or fatal. As regards compensation, the analogy is less exact because long-standing compensated renal failure is a much rarer phenomenon than compensated cardiac failure, and is seldom compatible with prolonged good health.

The conception of compensation and decompensation in renal failure depends on recognising that the main function of the kidney is the elimination of those superfluous chemical products which are found in the urine, nitrogenous matter, particularly urea, being the most important. In order that the elimination of these bodies may be accomplished with a minimal loss of water the kidney has the power of concentrating many of them in such a way that normal urine exhibits an enormously greater concentration of urea than does the blood. The damaged kidney shows its failure first of all by a loss of this concentrating power; it still succeeds in eliminating the daily quota of urea and other substances, but can only do this by pouring them out together with considerable amounts of water. In consequence of this we have polyuria as the first sign of renal failure, and this polyuria is a compensatory process because the kidney is still fulfilling its major function of maintaining the blood chemistry practically constant.

---

* A communication to the Assurance Medical Society on Nov. 2nd, 1932.

If renal failure persists the kidney becomes unable, even with the aid of increased water excretion, to rid the blood entirely of excess of urea. Uncompensated renal failure is then present and change in the blood chemistry can be demonstrated, this change being most often in the form of an increase in the urea and non-protein nitrogen. The following Table represents the main findings in compensated and uncompensated renal failure :—

—		Renal failure.	
		Compensated.	Uncompensated.
Urine	S.G.	Never above 1020.	Seldom above 1015.
	Urea	Below 2 per cent.	Below 1·7 per cent.
Blood		Urea below 40 mg.	Urea 40–300 mg. N.P.N. 40–300 mg.
Symptoms		Polyuria.	Polyuria. Gastro-intestinal symptoms.

It must next be emphasised that renal failure is a disturbance of function which may occur in any form of renal disease. It may occur during an acute nephritis or as the termination of a chronic nephritis. or it may occur in such conditions as damage to the kidneys from prostatic obstruction, polycystic disease, or tuberculosis of the whole urinary tract. It is a clinical state and not a disease in itself, and the prognosis, when it is present, depends on the disease causing it and the therapeutic possibilities which such disease may exhibit.

Uræmia and Pseudo-uræmia

The understanding of the conception of renal failure is important because it is now considered that uræmia is explicable by the ancient conception of Bright—namely, that it is a chemical intoxication largely due to the accumulation of urea in the blood. For several generations this conception has been rejected because of the frequency of persons dying with obviously diseased kidneys but without any notable increase in the concentration of urea and non-protein nitrogen in the blood. Observers therefore sought for some toxic substance other than urea which might be the principal agent producing uræmia, and it was commonly believed that nitrogen retention, when present, was merely an index of disordered blood chemistry, and that the unknown toxin responsible for uræmia might be present in the absence of these other signs. To-day it is believed by the group of workers to whom I have referred that the term uræmia should be reserved solely for those cases in whom there is gross nitrogen retention. We recognise a condition of compensated renal failure in which there is a normal blood chemistry maintained by the mechanism of polyuria ; we next recognise a condition of uncompensated renal failure with polyuria but with an increasing concentration of urea and other chemical substances in the blood ; and, finally, we recognise a condition of true uræmia in which the blood-urea has become enormously elevated, giving figures always above 150 mg. per 100 c.cm. and usually in excess of 200.

This condition of true uræmia is characterised by gastro-intestinal disturbance and deepening coma. Other manifestations, air-hunger, twitching, and so forth, often accompany it, but these are not essential ; they are the results of varying secondary changes in the blood chemistry, such as lowering of the alkali reserve and hypocalcæmia. If I were asked for the most characteristic clinical sign of true uræmia I would say that it is the occurrence of a metallic or ammoniacal taste in the mouth due to the presence of large quantities of urea in the saliva, and not infrequently recognised as such by the patient.

If this is true uræmia, what is the explanation of the many fatal cases of coma without changes in the blood, but with obvious renal disease at autopsy ? The answer is that these latter are examples of pseudo-uræmia in whom renal disease is accompanied by changes in the cardiovascular system, and that it is this cardiovascular change which produces cerebral effects leading to coma and death. It is often a matter of considerable difficulty to distinguish between the two groups on clinical examination alone. The pseudo-uræmic group is always characterised by elevation of the blood pressure, whilst the evidences of chemical derangement are slight or absent. The fact that these cases are dependent on changes in the lesser arteries and on diminution of the blood-supply of the brain leads to the fact that changes in the retina are present in most of them, chemical changes in the blood and urine are not conspicuous and may actually be absent. In true uræmia, on the other hand, there may be no elevation of the blood pressure at all, eye changes are often absent, but examination of the blood invariably discloses the true diagnosis.

From the therapeutic standpoint the distinction between these two conditions is of the utmost importance, because in true uræmia the indication is to adopt measures such as protein starvation which may alleviate the chemical condition of the blood, whereas in pseudo-uræmia it is of cardinal importance to bring about a change in the cerebral circulation as rapidly as possible, and venesection, lumbar puncture, and the intravenous administration of hypertonic solutions often become of critical importance. A. M. Fishberg, of New York, who has done so much invaluable work on these questions, has also been responsible for the introduction of many felicitous terms which enable us to understand the modern view. He refers to the cerebral manifestations of high blood pressure as "hypertensive encephalopathy" and he would have us speak of "hypertensive retinopathies" in all those conditions where changes of the retina occur in the course of disease or the cardiovascular system include those examples where the kidney is also involved. Surely this is a change well worthy of general adoption. At a time when we know full well that the group of cases in which albuminuria is most conspicuous, that is to say in the nephroses, retinal changes are never observed, it is ridiculous to retain the term "albuminuric retinitis" for a condition which clearly has no necessary connexion with the presence of albumin in the urine.

The Classification of Nephritis

I have felt it necessary to bring before you the above considerations concerning renal failure and true and false uræmia before discussing the classification of nephritis, because I feel that a clear conception of these states is essential for an appreciation of the classification of nephritis which is becoming evolved largely as a consequence of such doctrine.

I hope that I may be forgiven if at this point I interpolate a brief account of classifications of nephritis which have found many adherents in the past, some of which are current at the present date.

It is impossible to approach the subject of classification without reference to the past, and I must remind you that Bright was exceedingly cautious in avoiding any hard-and-fast differentiation into groups. Study of the medical history of the last century indeed emphasises the lack of uniformity in teaching, although it was perhaps unfortunate that in the absence of unity of conception individual writers tended to be dogmatic in dividing renal disease into various groups. It was largely as the result of the work of Wilkes and of Bartels that it became customary to distinguish two main varieties of chronic nephritis to which were attached the terms "chronic parenchymatous nephritis" and "chronic interstitial nephritis," the former being essentially a condition characterised clinically by dropsy and albuminuria, and the latter one in which there was a small contracted kidney in a patient dying of uræmia or cerebral hæmorrhage without œdema. The supposed occasional transformation of a case belonging to one group into a condition which flung him into the other group has been the cause of bewilderment and despair to generations of medical students. Many names, such as those of Gull and Sutton and of Weigert, might be quoted amongst the pioneers who exposed the futility of this classification; their voices were unfortunately not heard, although the rapid growth of histological inquiry soon made it apparent to the pathologist that there was no justification for the acceptance of it.

The first decade of the present century saw the genesis of a "functional" classification of nephritis which originated in France following the revival of biochemical investigation, chiefly as the result of the observation of Widal and his school. This school sought to divide Bright's disease into a group of patients in whom the damaged kidney was unable to excrete nitrogenous substances and hence produced uræmia, with, in opposition to this, a group in which the disease produced failure to excrete chlorides and other salts and hence produced œdema. At the present time it is unnecessary to say very much concerning this classification beyond that it had a transient value in focusing attention on biochemistry, and that the course of time has amply demonstrated not only that many patients could be placed in both groups simultaneously, but that modern biochemistry has rejected the theory that there is a type of kidney essentially incapable of excreting chloride.

To-day we are approaching a classification which has a sound basis of morbid anatomy and is also compatible with the various clinical manifestations of nephritis. Admitting that the widespread body of observers to whom I referred in the opening paragraphs of this paper have not yet reached agreement as to details, it is becoming more and more generally recognised that three great groups are to be distinguished. Of these the central group is constituted by the true inflammatory diseases of the kidney following acute infections. This great group of glomerulo-nephritis may be subdivided into a relatively benign group in which scattered foci of inflammation arise during an acute infection, and a second group in whom the inflammation is spread diffusely through both kidneys. This latter subgroup includes all those serious cases of nephritis which, beginning usually as a streptococcal infection, are seen again and again in the medical wards of the general hospitals, and eventually terminate fatally, usually after a very chronic course. In very severe cases the initial effect may be so tremendous as to produce renal failure and death from uræmia. More often an œdema of gradual onset is accompanied by a slowly rising blood pressure, and after waxing and waning for long periods tends to subside as renal failure slowly appears. Death will occur from true uræmia or from cerebral hæmorrhage or from pseudo-uræmia, according as the factor of glomerular destruction or of increasing hypertension is predominant. (See Figure.)

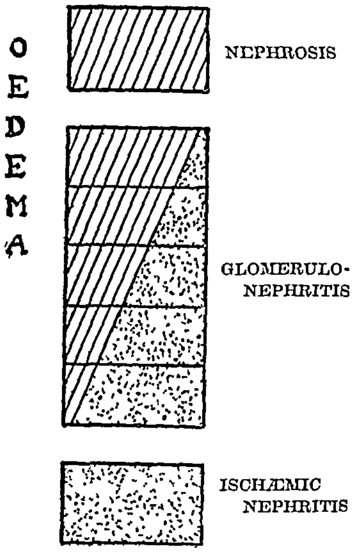

Diagram to illustrate the varieties and clinical phenomena of nephritis. Sub-varieties of glomerulo-nephritis are indicated. Shaded area = albuminuria; stippled area = hypertension.

Now in sharp opposition to this great group we recognise two other groups which have little if anything in common either with one another or with true inflammatory nephritis. The first of these is that which has been called "nephrosis." Here we have, clinically, an intense albuminuria, with or without œdema, but without either marked hæmaturia, increase in blood pressure, changes in the retinæ, or any tendency to uræmia. On the histological side we recognise the association of this group with kidneys showing no evidence of change in the glomerulus, but changes, purely degenerative in character, in the renal tubules. The recognition of this group is due largely to the work of Epstein, and if at the present day there is a tendency to reject his belief in the invariably benign character of nephrosis, it remains true that the prognosis in many examples is relatively good. Perhaps the most important lesson from his work has been that whereas even five years ago there was a tendency to say that renal œdema was an entirely mysterious phenomenon, it is now becoming agreed in all quarters that diminution of the density and osmotic capacity of the blood-plasma, following leakage of albumin into the urine, is the mechanical factor responsible for the production of renal dropsy. Examples of nephrosis are to be found in cases where the kidney has been damaged by the accidental or suicidal administration of mercurial poisons; another group is that known as lardaceous disease; but many cases have been reported arising apparently spontaneously. The great difficulty concerning nephrosis is that a certain number of these latter cases are found, with the passage of time, to develop hypertension and renal failure. These are examples which probably have been mistakenly diagnosed at the outset, being really cases of diffuse glomerulo-nephritis in which the initial glomerular damage was so slight as to escape recognition.

At the further extremity of the scale we find another main variety, contrasting vividly with nephrosis and constituting the third of the great main groups of renal disease. This is the division which includes all those cases in which the kidneys are damaged by changes in their blood-supply following some generalised vascular degeneration. Perhaps the best name to give to this group is "ischæmic nephritis." The outstanding clinical manifestation of these is hypertension, the outstanding feature of their morbid anatomy is sclerosis of the kidneys and spleen, with hypertrophy of the heart. Several subdivisions of this group are becoming recognised, but I do not wish to complicate the story by entering into fuller description of these beyond saying that far and away the most frequent cause of ischæmic nephritis is that mysterious condition which we speak about as "essential hypertension" or "hyperpiesia." I cannot too forcibly remind you that death in this group arises far more frequently from cerebral catastrophe or from cardiac failure than from renal failure: many authorities have stated their conviction that less than 10 per cent. of all such patients die of uræmia and renal failure, but many pathologists, finding in the post-mortem room a body with conspicuously shrivelled kidneys, incline even to-day to group all such cases as "chronic interstitial nephritis." Very brief histological examination of other organs, such as the spleen, should be sufficient to demonstrate that to regard such cases as primary diseases of the kidney is to fall into grave error. Sir William Gull, many years ago, had occasion to question the conception of the great Bright in this respect. Lecturing on some preserved specimens consisting of a large heart and two contracted kidneys, he said that not these alone but the entire man should have been included in the vase.

I do not wish it to be supposed that there are no clinical difficulties as regards the allocation of certain cases to this last group. True inflammatory disease of the kidney may be so insidious in its onset, and may be accompanied by such widespread arterial change, that hypertension is altogether predominant in the picture, but for every case of true chronic nephritis of this type there are probably 50 in which primary arterial disease is mistakenly classed as chronic interstitial nephritis.

Nephritis and Life Insurance

I fear it may be asked what practical bearing all this complex matter may have on life insurance examination. My reply is that although each of these groups represents a condition dangerous to the patient's life, the degree of danger varies considerably, and that the growth in popularity of short-term policies makes it expedient for us to be able to recognise those cases which are acceptable at increased premiums.

The first thing which I would stress from the point of view of life insurance examination is the extreme importance of accurate blood-pressure estimations in all cases falling into the category of nephritis. I think that it is a very serious mistake to reserve blood-pressure estimation for applicants in the last decades of life. Essential hypertension may appear at an age as early as 20. Minor degrees of renal damage in pregnancy may easily escape observation and may set up hypertension with fatal effects a few years later; I think that no woman who has borne children should be accepted for life insurance without very careful consideration of her history and of her blood pressure. The personal factor of the examining medical man is of course the great difficulty in this respect; the present generation of medical students is undoubtedly much better instructed as regards hypertension than were its predecessors, but it would be idle to pretend that the estimation of diastolic pressure, or even interpretation of it, is to-day a matter for any but the expert.

The next point I would emphasise is that careful examination of the urine remains of major importance, and that if no albumin is present on ordinary clinical examination it is practically impossible for renal failure even in its earliest stages to be present, and there is no indication that it is likely to occur at a later date. In other words, observation of the specific gravity of a urine which contains no trace either of sugar or of albumin is, for practical purposes, superfluous.

The determination of the prognosis in any single case belonging to any one of the groups I have mentioned must be a matter for expert consideration. Perhaps it is well to mention those signs which should lead to immediate and final rejection; of these I would say that definite changes in the blood chemistry and the presence of exudates or hæmorrhages in the retinæ are the most certain. At the other end of the scale I would say that qualified acceptance can usually be given with safety to cases of nephritis which, five years after onset, exhibit albuminuria as the sole evidence of disease, and that mild degrees of hypertension, without albuminuria, without cardiac involvement, and with a systolic pressure below 180 and a diastolic pressure below 100, tend to be far too heavily loaded at the present time.

It may seem that I have delivered a lecture of great complexity in order to conclude with a handful of platitudes. I can only plead that I have attempted to bring before you a conception of nephritis which holds out genuine promise for the future.

THE ANATOMY OF ASTHMA
AS DISCLOSED BY LIPIODOL INVESTIGATION

By J. B. Christopherson, C.B.E., M.D. Camb.,
F.R.C.P. Lond., F.R.C.S. Eng.
PHYSICIAN TO THE CITY OF LONDON HOSPITAL FOR DISEASES OF THE HEART AND LUNGS

(WITH ILLUSTRATIVE PLATE)

Although recent investigations into the bio-chemical, bacterial, and nervous relationships of asthma have rendered our knowledge of the disease less obscure, hitherto its pathological anatomy has remained entirely a matter for conjecture. The introduction of the use of lipiodol, however, promises to throw light on the subject by the opportunity it affords of studying anatomically the condition of the bronchial tree and its ramifications in the asthmatic patient, both during his paroxysms and in the intervals between attacks. Moreover, lipiodol by its therapeutic action may give a degree of relief even in intractable cases, which is well worth the apprehensive discomfort felt by the asthmatic patient when faced with the prospect of even a small operation.

Ordinary X ray examination of the chest has disclosed that in 300 consecutive cases of asthma 39 per cent. appeared normal and 61 per cent. presented complications [1] incidental to but not necessarily an essential part of asthma. In place of conjectural induction based on shadows of varying density, investigation of the bronchial tree in asthma by means of radio-opaque lipiodol affords sounder basis for differentiating the normal from the pathological, and will possibly hasten an advance hitherto denied owing to the lack of exact anatomical information which autopsy has failed to produce.

THE RESPIRATORY MECHANISM

Elsewhere I have dealt with asthma associated with chronic bronchitis, bronchiectasis, and the permanent irregularities of the bronchi revealed by lipiodol. *The present paper is restricted to a study of the* clinical complex known as the Trousseau type of asthma. Ætiologically this condition may be regarded as attributable less to morbid change than to physiological defect as the main factor: the result of what may be termed a delirium of the respiratory nervous control, brought about by incoördination of the respiratory autonomic mechanism, in which the vagus impulses dominate and sympathetic action is in abeyance. Whatever the immediate conjectural cause of that disturbance, whether chemical, mechanical, or psychological, the paroxysm produced would seem to be dependent on an inherited predisposition of the respiratory centre to respond to the stimulus of some biochemical agent, possibly a product of metabolism, or nutritional defect, as a sequel to the deprivation of necessary endocrine secretion or lack of simple salts.

---

[1] Bray, G. W.: Asthma, Hay Fever, Eczema, Migraine. London, 1932.

In the production of asthma there is, I would suggest, a definite and inseparable relation between the modes of action of the vagus nerve and of the sympathetic; and further, that whilst asthma is the clinical evidence of dominant vagus action, chronic bronchitis is the outward expression of sympathetic predominance. The close relationship between the two clinical conditions must be recognised as calling for their joint investigation before any real progress can be made in their cure. In the autonomic nervous system controlling the bronchial tree the functions of the vagus and sympathetic are antagonistic, the former constricting, the latter dilating the bronchi. Overaction of the vagus, productive of the clinical picture known as spasmodic asthma, suggests the possibility of the opposite phenomenon, dependent on dominant sympathetic impulses.

In normal respiration the dual nervous control maintains an even balance, the sympathetic exerting its influence in inspiration by causing some dilatation of the air-passages, the vagus in expiration by constricting them. In health there is physiological harmony and coördination between the two controlling factors. Disturbance of the balance allows prevailing vagus impulses to bring about spasmodic asthma; between the paroxysms sympathetic reaction, as a complementary part of the process of respiration, shows itself by the wheezing, associated with the complete freedom from respiratory obstruction, which brings relief to the victim. The dilatation of the bronchioles in asthma is the result of the predominant sympathetic action, which may involve the whole or part of the lung, or only a single branch of a bronchus. It is the distribution of this sympathetic control of the air-passages in clinical asthma which the use of lipiodol has been so successful in demonstrating.

TECHNIQUE OF LIPIODOL INJECTION

In my opinion examination by lipiodol is correct procedure for all asthmatic persons over the age of 10 years, whilst it may be administered with satisfactory results to younger subjects, as in one of my cases, a child 5 years old. Lipiodol, being chemically and physiologically almost inert, is not a bronchial irritant and seldom precipitates a paroxysm. But to anticipate any exacerbation during the process of injection, and to control the bronchial reflex, 10 minims of adrenaline 1 : 1000 are given to the asthma patient hypodermically immediately before the lipiodol is injected.

The small operation of injecting lipiodol is a procedure which requires a little practice. I personally inject via the cricothyroid membrane, using novocain ½ per cent. intradermally as a local anæsthetic; 7½ minims of cocaine 5 per cent. are next introduced into the (adult) larynx to abolish the cough reflex. The injection is given very slowly with a curved trocar and cannula of my own pattern. The lipiodol makes its way by gravity along the bronchial tree; if too much is given it may occupy the whole lumen of the tube and cause collapse of the lung, whole or in part, or imperfect distribution is likely to ensue. Lipiodol makes its way not only by gravity but by diffusion, spreading equally over the whole inner surface of the tube. The maximum for an adult is about 20 c.cm. More than this is apt to get into the alveoli, especially if the patient coughs and overcomes the sphincter action where the bronchiole becomes alveolus, or if there is frank emphysema. If the alveoli are injected then the bronchi will be obscured; one cannot see the branches of the tree for the leaves. For a child 3–5 c.cm. is enough. The few accidents which occur in lipiodol injections are due to failure in technique.

Provided there is no spasm of the bronchial muscles the radio-opaque lipiodol penetrates with remarkable freedom into the minutest ramifications of the bronchial tree and, unless there is emphysema or the patient coughs, it will stop short of the alveoli. If there is spasm of the bronchial muscles, or if there is spasm in a particular area of lung, it will not penetrate. Most of the lipiodol is coughed up; some may be coughed up and swallowed, when it will pass the stomach unaffected by gastric juice but, coming in contact with the lipase of the pancreatic juice, the lipiodol (which is a very stable oleate in an oily solution) is broken up and some, seldom serious, iodine intoxication may ensue.

DR. CHRISTOPHERSON: ANATOMY OF ASTHMA

Legends to Illustrations on Special Plate

FIG. I.—Spasmodic asthma; attack during injection. The lipiodol has not penetrated far into the bronchi owing to exacerbation of asthma during injection. Compare this film with Fig. II., where lipiodol has entered the bronchioles, the asthma being quiescent.

FIG. II.—Woman aged 32. Typical spasmodic asthma showing irregularity in outline of bronchi (beading). Network of small dilated bronchioles.

FIG. III.—Spasmodic asthma with some emphysema in upper and middle lobes of right lung.

FIG. IV.—Spasmodic asthma. Right side of the thorax. Some of the larger bronchi are dilated and varicose, retaining a good deal of the lipiodol, but the characteristic network of dilated small bronchioles is shown in the peripheral zones of the lung.

FIG. V.—Aggravated case of spasmodic asthma of many years' standing. On the right side the appearance is characteristic of lipiodol given a week previously; the remaining lipiodol is situated within the alveoli giving a punctate "scarlatiniform rash" pattern. Note on the left side, with lipiodol recently introduced, the network of dilated smaller bronchioles. In some places in the upper part of the lower lobe the lipiodol has entered the alveoli (showing emphysema). In the lower part of the left lower lung the bronchi appear like snapped-off sticks (better shown in the lateral view), probably due to local constriction of bronchi.

FIG. VI.—Lateral view of the right side of the thorax in case of aggravated form of asthma. Some of the larger bronchial tubes are varicose, but in the lower lobe they appear as if snapped off short (contraction due to local area of asthma spasm). The bronchioles in the middle lobe are dilated and some lipiodol has entered the alveoli (showing emphysema). Note the network of dilated small bronchioles in upper lobe, which is a characteristic appearance in asthma films.

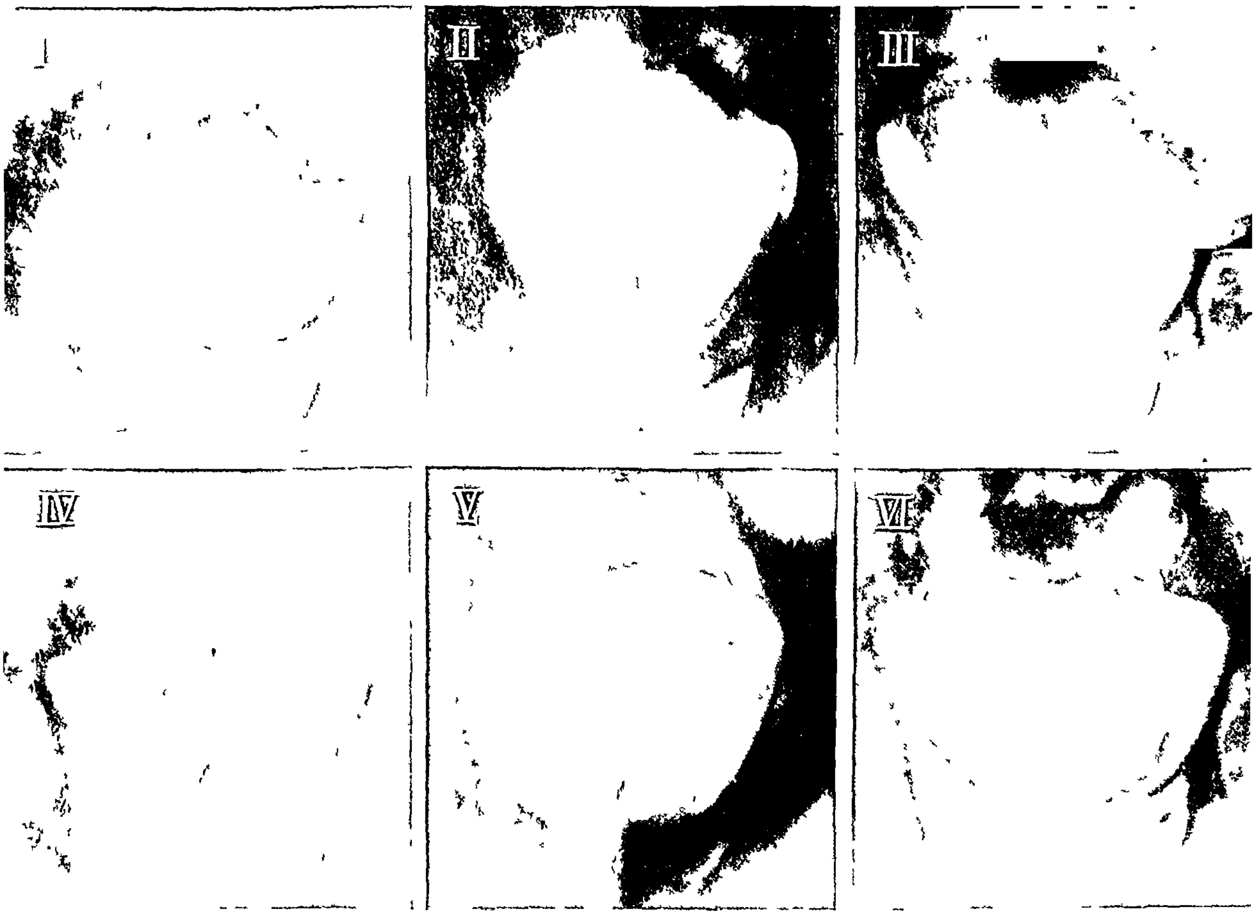
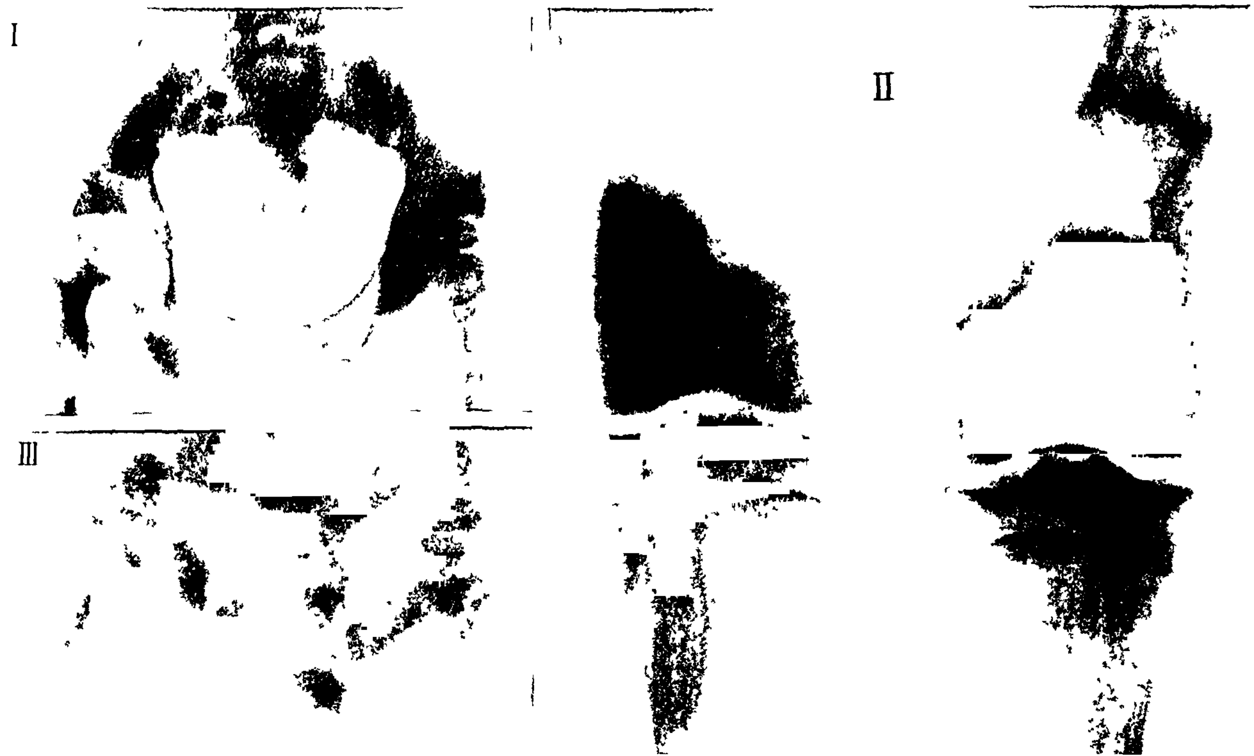
DR. ROSS· RADIOGRAPHIC DIAGNOSIS OF PROSTATIC ENLARGEMENT

(*Radiograms by Dr J F Bromley*)



DR BRAILSFORD SLIPPING OF EPIPHYSIS OF HEAD OF FEMUR



X RAY APPEARANCES

When examination by X rays is made directly after the introduction of lipiodol one of three pictures may be presented.

(1) The clinical condition of asthma is a general one, affecting the whole lung, with the bronchioles usually in a state of dilatation and therefore free to the passage of lipiodol into the entire bronchial tree. This, the most common condition, presents the characteristic mesh-like appearance of dilated bronchioles, together with irregular network of smaller tubules, whilst the larger bronchi show an apparently normal calibre. The potential sphincter at the junction of the terminal tubules with the alveoli generally, for the time being, prevents the further passage of lipiodol unless the patient happens to cough, thus relaxing the sphincter and allowing the succeeding inspiration to force fluid into the alveoli. In cases of emphysematous distension of the lung tissue, which entails loss of the sphincter control, similar entry of the fluid into the alveoli may occur. Even in the absence of cough or emphysema examination on the day following injection will show that the lipiodol has invaded the alveoli, yielding a typical punctate stippling or mottled cluster of grapes appearance (particularly in those portions of the lung which happen to be emphysematous), and presenting a marked contrast with the clearly outlined irregular network of the finer bronchial tubules due to sympathetic domination.

(2) According to the state of the bronchial tree the picture may show, in certain cases, a local or patchy distribution of the affected parts of the lung; constriction of the bronchioles in one area having prevented entry of the lipiodol and elsewhere, under sympathetic action, the dilated bronchioles having allowed the fluid to pass.

(3) Less commonly there may be shown little, if any, penetration of lipiodol into the tubes in consequence of sudden vagal constriction of the bronchi or bronchioles, as in the rare event of a paroxysm occurring during the operation.

These pictures are illustrated in one or other of the six radiograms I have selected, the legends of which speak for themselves.

CONCLUSIONS

In explanation of the more usual result of lipiodol injection, with its free entry into the whole bronchial tree, it may be suggested that, in ordinary cases of asthma, this quiescent stage marks the phase of sympathetic action responsible for the relaxation of the bronchial musculature and so the opening of the bronchioles. In the spasmodic stage the converse is brought about during the phase of vagal impulses leading to constriction and obstruction of the respiratory passages. The two phases of antagonistic nerve impulses governing the phenomenon of asthma, however, do not necessarily involve the whole lung, but may be confined in their action to a part of a lobe, to a single bronchus, or to an isolated area. Further it would appear that, in those who have suffered from asthma for some length of time, certain complications, made manifest by the use of lipiodol, have led to permanent dilatation of the alveoli—i.e., emphysema dependent on the mechanical effect of bronchial obstruction, the constricted lumen imposing a barrier to the forcibly expired air during a paroxysmal attack.

In some cases there is seen to have resulted a permanent dilatation of the bronchial tubes with beading and varicosity, possibly the effect of constant over-action of the sympathetic causing the relaxed tubules to become still further dilated by the explosive force of the asthmatic cough. On the other hand, the lack of evident change in the calibre of the larger bronchial tubes, in asthma as well as in chronic bronchitis, may be due to the cartilaginous support and the comparatively small amount of dilatable muscle in the bronchial walls.

SUMMARY

(1) Lipiodol affords a valuable means of studying by X ray examination the anatomical distribution of the bronchial tubes and their ramifications.

(2) Lipiodol will demonstrate the permeability of the bronchioles and smaller branches in asthma and bronchitis, whether in a state of constriction or dilatation, and the extent of free entry into the alveoli.

(3) The antagonism of the dual nervous control of the bronchial tree is demonstrable as playing an important part in asthma and chronic bronchitis—the vagus in causing constriction and the sympathetic dilatation of the bronchioles.

(4) Lipiodol is also of value from its therapeutic action in cases of the clinical complex known as asthma.

DR. ROSS: RADIOGRAPHIC DIAGNOSIS OF PROSTATIC ENLARGEMENT

Legends to Illustrations on Special Plate

FIG. I.—Normal aerocystogram. A rather large bladder.

FIG. II.—Large intravesical projection of prostate with a distended bladder.

FIG. III.—Same as Fig. II. after prostatectomy. Note the bed of the prostate, and the tags of tissue which have been left behind, and compare the capacity of the bladder in its present state with that before operation.

FIG. IV.—The prostate is enlarged and occupies almost half the bladder: the bladder wall is thickened and trabeculated but the bladder is not yet dilated (bladder in systole).

FIG. V.—Another example of enlargement of the prostate.

FIG. VI.—Same as Fig. V. after prostatectomy. The area to the right is a collection of gas in the colon.

DR. BRAILSFORD: SLIPPING OF EPIPHYSIS OF HEAD OF FEMUR

FIG. I. (Case 1).—Radiogram of the pelvis and hip-joints of a boy aged 16, showing on the left side marked slipping of the epiphysis of the head of the femur. Note the well-defined metaphyseal periphery of the epiphysis and the woolly outline of the extremity of the neck of the femur. On the right side there is thickening of the metaphysis; the epiphyseal border is well defined, whereas the diaphyseal border is woolly. Broadening of the sacro-iliac joints indicates similar disturbances of ossification.

FIG. II.—Radiogram of the knee-joints of the same patient as Fig. I. (taken on the same day), showing site of osteotomy of the right femur. Note the irregular extremity of the diaphysis of the fibula on the right side and the broadening of the metaphysis, with a regular epiphyseal border, indicating that growth is chiefly taking place from the diaphysis. The metaphyses of the other bones do not show any definite changes.

FIG. III. (Case 3).—Radiogram of the pelvis and hip-joints of a youth aged 21. There is general rarefaction and softening of all the bones as indicated by the woolliness of outline, the bending of the necks of the femurs, and the crushed triradiate pelvis. The metaphyseal borders of the epiphysis of the femur heads are still relatively well defined, but the outline of the extremities of the ends of the diaphysis is indefinite.

RADIOGRAPHIC DIAGNOSIS OF PROSTATIC ENLARGEMENT

By Norman Ross, M.B. Leeds

HOUSE SURGEON TO THE NORTH STAFFORDSHIRE ROYAL INFIRMARY, STOKE-ON-TRENT

(WITH ILLUSTRATIONS ON SPECIAL PLATE)

The prostate gland, lying as it does at the neck of the bladder, is in an unrivalled position, when diseased, to disturb the function of the bladder. In senile enlargement (to use a term which does not commit one as to the pathological process underlying the condition) we have a remarkable example of how the middle and lateral lobes have no other outlet for their expansion but to transgress upwards inside the sphincter vesicæ to the vesical outlet. Behind it is prevented from too great an expansion by the strong fascia of Denonvilliers, and below by the superior layer of the urogenital diaphragm. Apart from symptoms due to distortion and compression of the common ejaculatory ducts—e.g., aspermia or sexual neuroses—the urinary trouble will occur only when the intravesical enlargement has succeeded in elevating the apex of the trigone sufficiently to reduce the size of the bladder outlet by its ball-valve action. It is then that the patient complains of symptoms, and as the "hump" increases in size, so the symptoms increase in severity and frequency.

At this stage the practitioner relies solely on a rectal examination for confirmation of his diagnosis, whilst the urologist will employ his cystoscopic dexterity. If we disregard carcinoma of the prostate which is confined at first to the posterior lobe and initially produces more general and referred symptoms than local disturbance, and is not visible by cystoscopy until it has infiltrated and ulcerated through the mucous membrane of the bladder, cystoscopy has many disadvantages: (1) owing to contracture of the neck of the bladder it may be impossible to pass the cystoscope; (2) hæmorrhage from the passage of the instrument may cloud the field and prevent distinct vision; (3) gross sepsis may also cloud the field; (4) severe pain may necessitate an anæsthetic (general or spinal); and (5) an expert cystoscopist may not always be at hand.

Apart from these considerations, we are all familiar with the case of the man who has an unmistakably enlarged prostate when examined per rectum, but, on opening the bladder, is found to have either no intravesical enlargement or very little enlargement, but nevertheless has a contracture at the neck of the bladder which is responsible for his symptoms. This is the so-called "prostatic bar obstruction," "contracture of the neck of the bladder," or "prostatisme sans prostate." On the other hand, there is the patient who, from the history, has a typical enlargement of the prostate, yet on rectal examination shows little palpable enlargement; if we are successful in passing the cystoscope, we may find an enlarged middle and perhaps also lateral lobe elevating the anterior half of the trigone from the prostatic urethra backwards.

If any of the contra-indications to cystoscopy are present, absolute diagnosis between the two conditions—senile enlargement and prostatic bar obstruction—is a matter of uncertainty and guesswork, and as the latter condition does not necessitate an operation as serious as prostatectomy, the distinction is of some importance.

AEROCYSTOGRAPHY

The purpose of this paper is to emphasise the value of diagnosis of prostatic enlargement by aerocystography—i.e., radiography of the bladder after it has been filled with air. At the outset let it be understood that this is by no means an original method of diagnosis. Koller, in 1904, described a case of diverticulum of the bladder diagnosed by pneumoroentgenology, and the American radiologists have employed this method in the diagnosis of prostatic enlargement and in the visualisation of pelvic conditions causing pressure on the bladder. The technique is extremely simple, but differs somewhat from that of the authorities read. I regard this method as one of the essential links in the chain of investigations to be carried out in any case of suspected enlargement of the prostate. It is a rational proceeding, and one would expect it to be recommended and used generally although, in this country at any rate, this is not the case. The probable reason why it is not in general use is that cystoscopy has developed to such a degree that no other method is necessary unless cystoscopy fails. Where cystoscopy is unsuccessful, its value is obvious. Where cystoscopy is possible, aerocystography is still a valuable asset, and in my opinion gives a far more definite and helpful picture. It seems to me a superior method, because where a prostate is large its size cannot be gauged satisfactorily by cystoscopy, owing to the proximity of the lens to the gland. In a short series of 30 cases in which I have used the method the results are such that I have come to place absolute confidence in it. At the present time we would not consider cystotomy unless an aerocystogram had been taken previously.

Apart from enlargement of the prostate, aerocystography may be used in other conditions: (1) vesical calculi; (2) neoplasms; (3) foreign bodies; (4) compression from without—e.g., tumour of the uterus, ovary, or sigmoid; and (5) vesical diverticula. But as these conditions can be diagnosed more satisfactorily by other and simpler methods, such as cystoscopy in tumours of the bladder, I shall here only consider its practical application to enlargement of the prostate.

TECHNIQUE

The method can only be employed when the bladder is completely empty, and even small quantities of urine may obscure the picture. When the patient is admitted to hospital or nursing-home, if he has acute retention it will be necessary to tie a catheter in his urethra, this being done, of course, with the utmost sterile precautions. If there are 15 oz., or less, of residual urine, the whole may be decompressed at once, but if not, it will not be safe to remove more than 15 oz. at the time, the rest being withdrawn at the rate of 5 oz. every hour. It may take three or four days to completely empty the bladder, depending, naturally, on its capacity. Should there not be acute retention, the investigation can be carried out at any time.

When the bladder has been emptied as completely as possible and if the condition of the patient is good, the large rubber catheter is removed and a smaller one is substituted. It is essential that before taking the X ray picture the colon should have been well cleared out. The catheter I use is a No. 5 French. This should be new, or boiled at the most twice, since boiling destroys the rigidity of the rubber—a very necessary factor with small catheters required to pass through a contracture at the vesical outlet. It is better to use a small catheter than a large one with a small connexion, for the large diameter may obscure a small intravesical enlargement of the prostate. Once the catheter is passed, it is better to postpone injection of the air until the patient is on the Potter-Bucky diaphragm. To the distal end of the catheter is attached a 20 or 50 c.cm. record syringe (it will be found that this fits quite air-tight), the piston being withdrawn to its utmost. The patient is asked to relax the muscles and to refrain from straining as far as possible, and to give warning as soon as he feels that his bladder is full, or when he feels as if he wished to pass urine. The piston is gently charged home. The patient will say that he felt a "whiff of something" going into his bladder. The catheter is clipped with a Spencer Wells artery forceps by an assistant, the syringe is then detached from the end of the catheter, and the piston is again withdrawn to its utmost. With the piston at its utmost, the syringe is once more attached to the end of the catheter, the Spencer Wells is released and the piston charged home again. This process is repeated, the amount of air injected being easily estimated from the number of fillings required. Depending on the capacity of the bladder, a time will arrive when the patient will say his bladder is filled. If this is large, it will be seen distended above the pubes. If not, the patient's own sensations are not very reliable, especially in a nervous patient, and as it is necessary for a good film that no part of the bladder wall should be collapsed, it is better to rely on the actual pressure of the air inside the bladder. As soon as the bladder becomes over-distended there will be a positive pressure of its contents, which is readily gauged by releasing the Spencer Wells without removing the syringe; when, if a positive pressure really exists, the charger will come back on you. This is a most reliable sign, and it is then quite safe to occlude the catheter and take the radiogram.

The essential point in the radiography is that the kilo-voltage of the tube should be kept low, as is usual when dealing with a good background of air giving excellent contrast (40–50 K.V. should be quite sufficient). The obliquity of the tube is the same as for ordinary radiography of the bladder. Pfahler also takes a posterior film with the central ray directed obliquely upward and forward, so as to project the sacrum and coccyx above the field. I have found this unnecessary, since just as much information can be obtained from the anterior film. The posterior film is merely confirmatory.

It may seem a laborious process to remove and reinsert the syringe perhaps 20 or 30 times. American radiologists use a Higginson's syringe, which is certainly easier, but which lacks the ability to estimate the exact moment at which a positive pressure is set up within the bladder, and further, the exact capacity of the bladder cannot be easily estimated in this way. I have also used a pressometer, which would appear to be very exact, but in point of fact is not, because the surface tension of the mercury in the vertical tube is sufficient to overcome the first few millimetres of mercury rise, which are so important. Further, the capacity of the bladder cannot be estimated at all.

There is no danger of rupture of the bladder if the precautions stated are observed. The patient undoubtedly feels much discomfort, but as the bladder has only to be distended for a few moments whilst the film is being taken this is not a great inconvenience. Some difficulty is often experienced with a malignant prostate where the vesical sphincter is infiltrated with new growth, and where sphincter control is lacking, air being often forced out of the urethra outside the catheter, but even in these cases the taking of the film is so quick that enough air remains in the bladder to give good visualisation of its interior.

INTERPRETATION

Interpretation is easy. In an ordinary X ray film of the pelvis, very little, apart from the bony framework, can be seen in the normal case. It is possible to see vesical calculi, unless they are pure uric acid stones; also phleboliths. Tumours cannot be seen in the ordinary way (unless calcified—e.g., calcified uterine fibroid pressing on the bladder), and the explanation is simple. There is not enough contrast. I do not wish to make too much of this, however, for papillomata and carcinomata are best observed by cystoscopy. It is in enlargement of the prostate that aerocystography is of most value.

A normal bladder shows an outline of air, which is usually circular, and with absolutely smooth walls. Its capacity, as estimated by the number of fillings required, should be about 300 c.cm. When the film is taken at the correct angle the lower margin of the bladder should be seen about a quarter of an inch above the margin of the pubic bones (*Fig. I.*), quite distinct, running laterally within the ileo-pectineal lines to the iliac bones. The extent to which it rises above the promontoric line depends, of course, on its distensibility. With an acute retention of short history it usually remains within the pelvis, but with a long history its capacity may have increased to 600–900 c.cm., and it may rise as high as the upper margin of the ala of the sacrum and the fifth lumbar spine. This may not seem very high, but if it is remembered that the film is taken obliquely at an angle of about 15°–25°, it will be realised that the impression given is a false one, and that in reality the superior margin of the bladder is actually at a higher level than this. A large bladder is usually ovoid in shape owing to lateral compression in the pelvis, and may be displaced somewhat to the right by a loaded pelvic colon. Gas in the sigmoid often renders the picture indistinct, and it is therefore important to clear the bowel before the radiogram is taken. Often the contrast is so good when air is present in the rectum that it is possible to visualise the valves of Houston. With an intravesical enlargement of the prostate (middle and lateral lobes), the first thing that is noticed is the projection that it makes at the base of the bladder. It is quite definite, conical in shape and unmistakable. Its edges are continuous with those of the inferior vesical margin. There is no other shadow like it, and it is not very much less dense than the shadow thrown by the catheter itself (Figs. II. and V.). I have seen the fibres of the levator ani throw oblique, centrally converging linear shadows, but these again are unmistakable, and do not show when the prostate is much enlarged. In the female a similar shadow may be thrown by a cervical fibroid compressing the bladder.

Calculi are readily seen within the prostatic substance. If the swelling is seen to be smooth and regular in outline one would think of a benign enlargement of the prostate. If the upper surface is irregular in outline or the enlargement limited, especially to one lobe, one would think of a malignant condition, particularly so if there is infiltration beyond the normal boundaries.

Prostatic bar of obstruction of the glandular type (usually due to hypertrophy of the subcervical gland of Albarran) should be suspected if the symptoms are those of hypertrophied prostate, but no definite conical shadow is seen on the radiogram. There may be an indefinite blurring around the sphincter, but never the conical, sharp-edged shadow which is typical of the prostate. With a large fibrous bar of the trigone a well-marked shadow may be cast at the base, with a perfectly straight, horizontal, upper margin, running from side to side, and lying at a distance of ¼ in. to ½ in. above the lower margin, according to the depth of the bar.

The state of the bladder wall should be observed in all these cases. With a chronic retention of fairly long history as mentioned above, the upper border of the bladder will be seen above the ala of the sacrum, and the margin will be smooth and the wall thin. In a subacute obstruction, where the pathological process has been limited to muscular hypertrophy, the wall will be seen to be markedly thickened, and definite fasciculations can be seen (Fig. IV.). Should there be a diverticulum of the bladder, the margin is well shown, and also the cavity and neck. The presence of this can be confirmed by sodium iodide or lipiodol cystogram or by cystoscopy, if possible.

It is of interest to note the state of the bladder after prostatectomy. In these cases the shadow originally thrown by the prostate is no longer visible, and, furthermore, the actual bed of the prostate can be seen outside that area if the operation has been successful and there has been no recontraction of the vesical sphincter. The bladder is small. Its capacity may be half, or even less, of the original, showing that the obstruction has been relieved. Any tags of prostatic tissue or mucous membrane left behind, if big enough, can be seen quite clearly (Figs. III. and VI.).

It can confidently be stated that if the essentials above are observed, the exact state of the interior of the bladder is visualised. This has been confirmed time after time at operation. These essentials are: the use of a narrow rubber catheter sufficiently rigid to pass the contracture at the neck of the bladder; complete emptying of the bladder; introduction of sufficient air to just set up a positive pressure; correct angle of the X ray tube; and good preliminary clear-out of the bowel.

CONCLUSIONS

(1) Aerocystography is a valuable adjunct to all other methods of diagnosis of prostatic enlargement. (2) In addition, it tells us the state of the bladder. Diverticula and calculi are thrown into better contrast. (3) Where cystoscopy is impossible, it is the only method of visualising the intravesical enlargement. (4) The technique is simple, it is unassociated with any dangers beyond the ordinary ones of catherisation, and it gives valuable information. No anæsthetic is required.

I am indebted to Mr. T. H. Richmond and Mr. F. W. Duthie for permission to publish this work, which has been carried out in its entirety on cases under their care in the North Staffordshire Royal Infirmary, also for their kind advice and assistance; and to Dr. J. F. Bromley for his valued coöperation.

SLIPPING OF THE EPIPHYSIS OF THE HEAD OF THE FEMUR

ITS RELATION TO RENAL RICKETS

By James F. Brailsford, M.D. Birm.
HONORARY RADIOLOGIST TO THE ROYAL CRIPPLES' HOSPITALS, BIRMINGHAM

(WITH ILLUSTRATIONS ON SPECIAL PLATE)

The purpose of this paper is to show that renal rickets is the cause of a good proportion of the cases of slipping of the epiphysis of the femur, and arguments are deduced from the radiographic evidence against the more popular theory that trauma is the chief factor in its production. The importance of these findings is that operative measures designed to correct the deformity, heedless of the renal disease, may result in failure and may jeopardise the life of the patient.

Displacement of the epiphysis of the head of the femur usually results in the deformity known as adolescent or epiphyseal coxa vara. This condition is not uncommon—indeed, in young people between the ages of 12 and 21 years it has a frequency equal to that of tubercle of the hip-joint commencing at this period, and as the clinical signs of the two conditions are often indistinguishable, though the treatment and prognosis are so different, correct diagnosis is essential. In pre-radiographic days the lesion was discovered on a number of occasions only during or after resection of hip-joints which had been diagnosed as tuberculous. In a previous paper I have pointed out that by means of radiography it is now possible to differentiate between the various diseases and abnormalities of the hip-joint. In the series there described 26 cases of slipped epiphysis of the femoral head were observed—18 in males and 8 in females. Of the 18 males the slipping was on the left side in 13, in the right hip in 4, and in the other the epiphysis of both femurs had slipped. In one case, though definite slipping had only taken place on one side, the metaphysis of the opposite side was widened and its borders irregular, suggesting a pre-slipping stage. Of the females it was on the right side in 5 and on the left in 3. The condition therefore appears to be commoner in the male on the left side.

Radiographic Appearances

The radiographic appearances of the slipped epiphysis of the head of the femur are characteristic (Fig. I. on Plate). The epiphysis has a very clearly defined and regular metaphyseal periphery as if outlined by a pencil, its convex articular border being regular except for the fovea. It is in the form of a cap which appears to have slipped off the upper convex extremity of the neck of the femur, the margins of which are higher than the corresponding margins of the epiphysis, the deformity depending upon the degree of slipping. The pressure of the upper end of the neck against the "freed" crescentic epiphysis, which is applied to the articular surface of the acetabulum, tends to increase the displacement by causing the epiphysis to slip in the acetabulum downwards and backwards with some inward rotation. In cases with extreme displacement the upper end of the diaphysis comes into apposition with the superior border of the acetabulum, and the metaphyseal surface of the epiphysis is forced against the *inferior surface of the neck of the femur*. There is no irregularity of the bone trabeculæ or surfaces to suggest bone disease or injury. The joint space and the acetabulum appear to be unaltered. The convex upper margin of the diaphysis is usually not so clearly defined, and its outline appears to be woolly.

Though coxa vara is the usual deformity produced, Scheuermann has described and illustrated with radiograms a slipped epiphysis in which a coxa valga deformity resulted. Owing to the fact that patients who develop this deformity often complain of pain or discomfort in the region of the hip-joint for some weeks or even months before the actual slipping occurs, a radiographic examination is sometimes made and will often show the pre-slipping condition. This is important, for it will suggest treatment designed to prevent the slipping, and any investigation and treatment which will do this should be rigorously pursued because radiograms show that, once the epiphysis has slipped, the best result possible will be complete reduction with premature fusion and stunted development resulting in some degree of shortening. (Mr. S. T. Irwin has described the best result I have seen: only ¼ inch of shortening without any arthritic changes.) On the other hand, in spite of complete reduction, the epiphysis may undergo degenerative changes and result in a very disabling deformity for the patient. Incomplete reduction results in a joint prone to very early chronic arthritic changes with consequent disablement.

The radiographic features of this pre-slipping stage should therefore be sought in children suffering from discomfort or pain in the hip-joint. The clinical features may suggest early tuberculosis, but the radiogram shows bone of normal density and a regular outline of the borders of the epiphysis and diaphysis, with no evidence of any erosion or destruction of the bone lamellæ, which on repeated examination will rule out tuberculosis. All that is shown is some increase in the density of the metaphyseal periphery of the epiphysis—the "pencil lining" already described—some increase in the thickness of the metaphysis in part or throughout its whole breadth, with some woolliness of the outline of the extremity of the diaphysis (Fig. I., right side). I have one case of slipped epiphysis in which the radiograms show fragmentation with splaying out of the roof of the acetabulum (resembling Perthes's disease of the femoral epiphysis), which later radiograms show to have consolidated. This is a rare finding in these cases.

Ætiology

Numerous investigations of the cause of this condition have been made. The opinions of the investigators can be grouped under three headings: (1) disease, (2) weight-bearing and strain, (3) trauma. Personally I hold that each of these factors comes into operation to some degree; there is some disorganisation of the metaphysis which lessens its capacity to withstand the normal shearing stresses and strains, and the condition may be brought sooner into prominence by some trauma which would not have affected the normal femur.

DISEASE

Acute pyogenic infection of the hip-joint very commonly destroys the metaphyseal tissue and results in the separation of the epiphysis as a sequestrum. Lindemann has reported a case occurring in a child of 12 who was a congenital syphilitic, suggesting that the metaphysis was disorganised by the syphilitic process. Froelich, Platt, and others consider that the separation is brought about by a low grade of sepsis.

Localised osteochondritis and disturbances of endocrines, as instanced in the adiposo-genitalis type of dystrophy, have been put forward as the causative factor. Schwartz stated as his opinion that separation of the normal epiphysis was not possible, and that it was due to some unknown disease of the cartilage.

Many observers, notably Block, Fiorani, Frösch, Hofmeister, Haedke, Müller, and Peltesohn, have suggested rickets as the causative factor, though many others have strongly opposed this theory. Key, who has published the results of an extensive investigation of the published cases, as well as the findings in a number of cases which he has examined, states: "The only abnormality thus far detected is a slight broadening of the cartilage of the epiphyseal line. At this period some change occurs in the region of the epiphyseal line which causes a weakening of the structures which bind the head to the neck of the femur. The nature of this change is unknown, as no such case has ever been studied pathologically," and later: "It is further to be noted that in frankly rachitic children I have never seen a case of separation of any epiphysis, nor have I been able to find a single such case in the literature."

Do not the following facts concerning renal rickets supply this deficiency?

RENAL RICKETS

The histories of the following cases of renal rickets, together with the radiograms, undoubtedly place this as a very definite cause of this lesion.

In the paper already mentioned I said that "slipped epiphysis appears to be due to some disintegration of the metaphysis rather than direct trauma, as most of the patients with this condition give no history of trauma and the radiographic appearances do not support the trauma theory." Since this was written a patient, a boy aged 16, was sent to me for X ray examination of the hip-joints (Case 1). The radiogram of the hip-joints (Fig. I. on Plate) showed that the epiphysis of the one side had slipped and the metaphysis on the other was thickened—the pre-slipping stage. I obtained the history that one year previously the patient had had an osteotomy of the lower end of the femur for the correction of knock-knee, so I made radiograms of both knees to see if they would throw any light on the pathology. These showed (Fig. II. on Plate) a definite thickening of the metaphyseal area of the upper end of the left fibula but no such change in the metaphyses of the lower ends of the femurs or upper ends of the tibia or the right fibula. From these appearances I suggested the diagnosis of renal rickets, which was confirmed later by the characteristic appearances of renal rickets in the epiphysis of the radius and ulna. The urine was shown later to contain a large amount of albumin. No suggestion of renal disease had been previously suggested.

More recently another patient (Case 2) was sent for radiography of the knee-joints. These radiograms showed that the lower epiphyses of both femurs had a slight degree of slipping, while the metaphyses of the upper ends showed the appearance which I have described as the pre-slipping condition. I again suggested that the condition was that of renal rickets and urine examination revealed much albumin. Radiograms of the upper and lower ends of the tibia, fibula, radius and ulna and upper ends of the humerus showed a similar thickening of the metaphyseal area. Yet radiograms of these same areas only one month after showed a most remarkable improvement; the metaphyses appeared to be almost normal. The radiograms of the long bones in these cases do not show the characteristic appearances seen in the radiograms of frank rickets. There is no suggestion of bowing of the long bones or bending of the neck of the femur; except in the immediate neighbourhood of the metaphyses, the bones appear to be normal in density, and in the last radiograms of Case 2 little indication of the past, though recent, metaphyseal disturbance is to be detected. Parsons and Teall have described and illustrated a case of atrophic rickets with a four years' interval between the radiograms, showing complete disappearance of the signs of active rickets, though the bones appear in the healed condition to be rarefied, and they have pointed out that "the changes do not occur to the same degree in all the long bones—e.g., the radius and ulna of one arm may show changes much more marked than in those of the other side."

This observation is confirmed by Figs. I. and II., and proves that it is possible for renal rickets to cause a disintegration of the metaphyses of the upper end of one femur with resulting slipping without there being any further radiographic evidence of renal rickets.

In the type of renal rickets which Parsons and Teall describe as "woolly" the bones are generally softened and bend with pressure as in osteomalacia, which would appear to spare the epiphysis from separation. Fig. III. (on Plate) is a radiogram of the pelvis of a youth aged 21 (Case 3) with renal disease which has resulted in this "woolly" type of rickets. The pelvis has become triradiate. The epiphyses of the femoral heads show the sclerosed margin and the thickened metaphyses, but instead of the epiphysis slipping bilateral coxa vara deformity has resulted from marked bending of the necks of the femurs. Owing to the gravity of his renal disease he cannot stand, consequently the femoral metaphyses are not subjected to the strain of the erect position which the less disabled patient is allowed to endure.

The radiographic evidence of these cases of renal rickets proves therefore that this condition can induce slipping of the epiphysis of the head of the femur and even of other epiphyses. The rapid disappearance of the active rachitic changes at the metaphysis, as illustrated in Case 2, in which one month after marked changes were shown on the radiograms, the metaphysis was almost indistinguishable from the normal, would account for the objections of many observers who have stated that the bones showed no evidence of rickets. I have examined the urine of two further cases of slipped epiphyses which have united and found much albumin, though the bones do not show the changes I have described. Haswell Wilson reported that the metaphyseal tissue in a case of renal rickets, cited by Parsons, was indistinguishable from florid rickets, and microscopical examinations of the metaphyseal tissue of the hip-joints excised by Kocher, Frangenheim, and Haedke revealed alteration in the cartilage and the presence of osteoid tissue.

I am convinced, therefore, that renal rickets can be a definite cause of slipping of the epiphysis of the head of the femur. Lindemann has shown that this can also occur as a result of congenital syphilis in the radiograms of the joints of which we see somewhat similar changes in the metaphyseal regions. There are probably other excretory or secretory disturbances which produce this metaphyseal disorganisation which we should endeavour to determine.

STATIC CAUSES

It has been suggested that the condition can be induced by strain due to long-continued standing or by the superincumbent weight of the trunk, particularly in the obese patient, or by the increased strain thrown on one hip because of disease or deformity of the opposite hip. It has been suggested that this weight or strain led to the bending of softened rachitic bone of the neck of the femur which ultimately led to separation of the epiphysis. This is not supported by radiography. The femoral epiphyses which have slipped appear to be always associated with femoral necks which show no evidence of bending. I have a number of cases in which the radiograms show extreme coxa vara deformity owing to bending of the neck of the femur due to rickets, but only one of these show the slightest evidence of displacement of the epiphysis. This exceptional finding I believe to be due to an osteotomy which placed strain on a metaphysis in an active phase of rickets. The radiograms of the patient (Case 4), a girl of 6, showed a triradiate pelvis with marked bowing of the neck of the femur on both sides. A bilateral osteotomy of the upper third of the femur was performed. Radiograms taken six years after showed that the epiphysis of the left femur had slipped. In the radiograms of the long-standing case of renal rickets (Case 3), though the metaphyses show marked degenerative changes, no slipping is shown but marked bending of the neck of the femur. That the shearing strain on the metaphysis due to the superincumbent weight and muscle pull causes the displacement of the epiphysis I have little doubt, but it only happens after the metaphysis has been disorganised—it could never happen with a normal metaphysis.

TRAUMA

The first case of displaced epiphysis of the head of the femur was discovered by Brousseau in 1867 at the autopsy on a boy, aged 15, who had received his fatal injury when a vehicle passed over his hip-joint. But Rammstedt was unable to produce simple separation of the epiphysis experimentally.

Elmslie, Rammstedt, and others have suggested that trauma loosens the head epiphysis and that it gradually slips afterwards. Radiographically there is nothing to support the traumatic theory except that trauma insufficient to cause any displacement of the normal epiphysis may result in the displacement of an epiphysis with a disorganised metaphysis.

I have never seen a simple separation of the epiphysis of the head of the femur when a child has been brought for radiography because of a recent severe injury to the region of the hip, though I have seen a number of fractures in the neighbourhood of the metaphysis in such patients. On the other hand, one readily receives information as to past injuries if a child is brought complaining of pain or discomfort in the hip-joint, though there is no bruising or other clinical evidence of such an injury. If trauma is alone responsible, one would expect to see separation of the epiphysis after manipulative procedures to reduce congenital dislocations. Radiograms show that the trauma in such procedures is often sufficient to result in fragmentation of the epiphysis or even fracture of the neck or shaft of the femur, but I have never seen a simple separation of the epiphysis either immediately after, or with a long interval, which might be expected to happen if the epiphysis had only been loosened.

Radiograms also show that when an epiphysis has been displaced by trauma, portions of the metaphysis are also displaced with it—i.e., it is not a clean separation through the metaphysis as we see in slipped epiphysis. Bilateral slipped epiphysis is not a very uncommon finding. Hofmeister reports that one-third of his cases were bilateral. While a patient is receiving treatment for one slipped epiphysis separation of the opposite femoral epiphysis may occur. I have only one example of a bilateral fracture of the neck of the femur in an adolescent—it is a very rare occurrence; in this case, as in all the other fractures of the neck of the femur, there is no suggestion of a simple separation through the metaphysis. Many of the patients with this displacement have complained of pain or discomfort in the affected hip-joint for weeks or months before the trauma occurred. This pain or discomfort has been often brought on by fatigue and relieved by rest, which in itself suggests the hip-joint was not normal, and, as previously stated, it is rare to find bruising or evidence of recent severe trauma when the radiogram shows a simple epiphyseal separation.

Conclusions

(1) Slipping of the epiphysis of the head of the femur in adolescents is due to disorganisation of the metaphyseal tissue which destroys its capacity to withstand the static strains or the trauma to which the normal joint is subjected without harm.

(2) Renal rickets is the cause of this disorganisation of the metaphysis in some cases, and should be excluded before any operative measures are adopted.

(3) The radiographic picture of renal rickets is almost diagnostic; the changes may only be seen in one joint.

(4) Consolidation and repair of the metaphyseal tissue in renal rickets may be seen by radiographic examination to take place in as short a time as one month.

(5) The urine of all patients showing slipped epiphysis should be examined on several occasions for albumin. The radiographic appearance of the bones in renal rickets is to some extent an index of the renal condition.

FACIAL PALSY AND INFECTION WITH ZOSTER VIRUS

By R. S. AITKEN, M.B.N.Z., D.PHIL. OXF., M.R.C.P. LOND.
FIRST ASSISTANT TO THE MEDICAL UNIT, LONDON HOSPITAL
AND
R. T. BRAIN, M.D., M.R.C.P. LOND.

(From the Medical Unit and the Freedom Research Laboratory, the London Hospital)

IN 1907 Ramsay Hunt[1] wrote his classical paper on Herpetic Inflammations of the Geniculate Ganglion, in which he drew attention to the occurrence of herpetic eruptions in or near the external auditory meatus along with facial palsy, and sometimes with lesions of the eighth cranial nerve; and he brought evidence to show that the seventh nerve has a somewhat rudimentary sensory supply, overlapping that of adjacent nerves, to the tympanic membrane, the external auditory meatus, and the adjacent parts of the concha. Since then his syndrome has been generally recognised, and his explanation of it as a specific zoster infection of the geniculate ganglion is widely accepted. The extent of the zoster eruption varies a great deal, and the extent of the cutaneous supply of the seventh may also be presumed to vary; the question therefore arises whether any cases of this condition occur in which, owing to smallness of the cutaneous supply or for some other reason, the eruption is missing. If so, they would appear clinically, if the eighth nerve is not involved, as cases of ordinary Bell's palsy. Antoni[2] raised this question in 1919, but so long as the only known diagnostic characteristic of zoster was its eruption, it could not be answered. Recent serological work, however, has provided a new method of approach.

Although zoster is always included among the diseases due to filtrable viruses, direct evidence in support of this has not yet been produced. It is inferred from the failure of all efforts to find a cultivable bacterium in the fluid of early vesicles, and from the presence of nuclear inclusions, similar to those produced by the virus of herpes febrilis, in the epidermal cells of the lesions. In addition, Kundratitz[3] claims that, in a high percentage of susceptible children, zoster vesicle fluid inoculated into the skin produces a vesicular lesion, followed occasionally by a generalised eruption of a similar nature; more rarely the generalised vesicular eruption occurs without any preceding local lesion. Bruusgaard[4] has confirmed Kundratitz's findings. Netter[5] and his colleagues have produced evidence that the serum of zoster convalescents contains a specific antibody whose presence can be detected by the complement-fixation reaction, using as antigen diluted zoster vesicle fluid, or a suspension of crusts from zoster skin lesions. Lauda and Silberstern[6] failed to confirm this, but the observations of Bedson and Bland,[7] though limited to a small series, support Netter's claim, and in a series of 82 convalescent zoster patients shortly to be reported by one of us (R. T. B.) positive complement-fixation reactions were found in 80.

Zoster may therefore be regarded as an infection with a specific virus, which leaves evidence of itself, after the illness has passed, in the form of antibodies in the serum, and if any cases of Bell's palsy are due to this virus the complement-fixation reaction should reveal evidence of this.

We have carried out this reaction with sera of a number of such cases, using essentially the technique described by Bedson and Bland.[7] The specific antigen was a 1 in 20 dilution of vesicular fluid from early zoster lesions in M/50 phosphate buffer solution at pH 7·6. We also tried antigen prepared from the scabs of older lesions (Netter) but found them strongly anticomplementary and much less satisfactory than the diluted vesicular fluid. The antigenic potency of the latter varies considerably; hence, although Netter worked with a 1 in 100 dilution, and in one of our own cases a 1 in 160 dilution was found effective, we preferred to adopt a 1 in 20 dilution for routine use. The control antigen was a bullous fluid from the lesions of a patient with dermatitis herpetiformis, similarly diluted. Antigens were usually bacteriologically sterile, in which case, when stored in a refrigerator, they kept their antigenic properties for some months. The diluted antigens were tested for anticomplementary action in the presence of 1 M.H.D. (minimum hæmolytic dose) of complement on the day of the test. Occasional samples proved to be anticomplementary but it was found that heating for ten minutes at 56° C. removed this property. The sera were used undiluted after having been inactivated by heating for 20 minutes at 56° C.

In each series of tests 0·1 c.cm. of the serum under investigation, 0·1 c.cm. of antigen, and 0·1 c.cm. complement (containing 2 M.H.D.) were mixed in that order, and the volume made up to 0·8 c.cm. with saline. After the mixture had stood two to three hours at room temperature, 0·2 c.cm. of sensitised sheep red cells was added, and the whole incubated at 37° C. for 30 minutes. The degree of hæmolysis was read immediately, and again after 24 hours in the refrigerator. With each group of sera the following controls were put up and treated in the same manner: at least one serum from a patient convalescent from ordinary zoster; at least one serum from a normal person or a patient who had not recently suffered from either zoster or chicken-pox; antigen and complement; antigen without complement; serum without complement; complement alone.

The cases fall into two clinical groups.

CASES WITH CUTANEOUS ERUPTIONS

Group I.—Eight cases of Bell's palsy with clinical evidence of cutaneous eruptions in the neighbourhood of the ear and one case with an eruption on the tongue. Their clinical features were briefly as follows:—

CASE 1.—A woman, aged 41, complained for two or three days of severe pain round the left ear, radiating down the neck and over the temple. Then a few "water blisters" appeared behind the ear and on the pinna, and others on the left upper arm, the left temple, and just inside the hair line on the left side of the head. She felt soreness inside the left external auditory meatus but there was no aural discharge. Severe pain persisted for 15 days, became worse on the sixteenth day, and on the seventeenth she woke with a complete left facial palsy. On examination the following day, slight œdema and marked tenderness were found over the mastoid process; small scabbed areas were present on the pinna and behind the ear; the drum was normal but a small vesicle was seen close to it on the posterior meatal wall. The œdema persisted for a week, and the pain, gradually diminishing, for a few days longer. The facial nerve recovered its function in about four weeks. Serum obtained seven weeks after the onset of the paralysis gave a positive zoster complement fixation.

CASE 2.—A man, aged 59, who had never had shingles and could not remember chicken-pox, complained for seven days of moderately severe aching pain extending from behind the left eye to below the left ear. Then he had a sore-throat, and two days later a left facial palsy appeared. About the same time a vesicular rash was observed, chiefly behind and below the left ear and in the concha, with outlying single vesicles above and in front of the ear, on the bridge of the nose, and above the left eyebrow. There was a slight discharge from the left ear, impairment of hearing on that side, and slight impairment of taste on the left side of the tongue. Serum obtained 12 days after the onset of the paralysis gave a positive zoster complement fixation. The eruption healed, but the face recovered only very slowly, being still weak 14 months later.

CASE 3.—A man, aged 57, suffering from tabes dorsalis, with positive Wassermann reaction in blood and cerebrospinal fluid, complained one day of slight discomfort in the right external auditory meatus, and was found to have a right facial palsy. Two days later a crop of vesicles appeared round the external auditory meatus, and one vesicle just below and behind the lobule of the ear. There was loss of taste on the right side of the tongue. Serum obtained 20 days after the onset of the paralysis gave a positive zoster complement fixation. Five days after his eruption appeared, a nurse on duty in the ward where he was a patient developed a patch of herpetic vesicles over the sacrum, preceded by pain for one day; 11 days after this a boy, aged 8, a patient in the same ward, developed chicken-pox.

CASE 4.—A girl, aged 13, who had chicken-pox in infancy, but never shingles, complained of left-sided earache for about a week. She became ill, with vomiting, abdominal pain, and generalised headache, but with a reputedly normal temperature. Then her mother noticed several blisters containing watery fluid in the concha of her left ear. Three days later left facial paralysis occurred, after which the general condition gradually improved, though when she first got up she complained of giddiness and stumbling. Serum obtained 17 days after the onset of the paralysis gave a positive zoster complement fixation. Recovery was complete in about six weeks.

CASE 5.—A woman, aged 60, who had never had chicken-pox or shingles, complained of severe pain over the right ear and down the right side of the neck for one day, and then noticed right-sided facial paralysis. Shortly afterwards she felt, but did not see, a "pimple" in the floor of the entrance to the right external auditory meatus; it dried up, and a "scurfy patch came off." On examination four weeks later, an almost complete right facial paralysis was still present, but the ear appeared normal. Serum obtained then gave a partially positive zoster complement fixation. The pain lasted, with diminishing intensity, for about a fortnight.

CASE 6.—A man, aged 36, who had never had chicken-pox or shingles, woke one morning to find his right face paralysed and saliva dribbling from his mouth. Five days later he had a little transient pain below the right ear. Examination ten days after the onset showed an almost complete right facial paralysis without disturbance of taste, and a scaly, partly scabbed eruption in the concha of the right ear at the entrance to the meatus, on an area of raised red cracked skin. There was debris in the meatus; no actual vesicles were seen. The patient had first noticed this condition two days previously. Serum obtained ten days after the onset of the paralysis gave a positive zoster complement fixation. Recovery took about a month. He had had right-sided otorrhœa in childhood, with subsequent slight deafness.

CASE 7.—A man, aged 26, had complained for six months of "headache" in the right mastoid region, and for five years had had slight bilateral aural discharge. He had never had shingles and could not remember chicken-pox. He developed a cold, with a cough, and noticed a "queer taste" on the right side of his tongue. Five days later his right face became paralysed. Six days after that, examination showed a complete right facial paralysis, with no impairment of taste, and a slight scabbing on the posterior wall of the entrance to the right external auditory meatus. The drums showed signs of old chronic otitis media, without recent activity. Serum obtained nine days after the onset of the paralysis gave a positive zoster complement fixation. Recovery took about four weeks.

CASE 8.—A girl, aged 15, who had had chicken-pox in early childhood, but never shingles, had a little left-sided earache, and her mother noticed what she described as one or two "purulent spots" in the left external auditory meatus. Seven days later left facial paralysis appeared, and was almost complete when she was examined after a further interval of three weeks. She had no severe pain, and taste was unimpaired. Serum obtained then gave a positive zoster complement fixation.

CASE 9.—A girl, aged 13, who had had chicken-pox as a baby, but never shingles, developed a "cold," and complained for three or four days of a nagging pain over the tip of the right mastoid. Then the right side of the face suddenly became paralysed, and she noticed impairment of taste on the right side of the tongue. On examination four days after the paralysis, two yellow pin-head vesicles, very close together, surrounded by a red area, were seen at the tip of the tongue on the right side; serum obtained at the same time gave a positive zoster complement fixation. The vesicles disappeared in a few days; the paralysis persisted for at least two months, after which she was lost sight of.

These nine cases had cutaneous eruptions in the area of supply of the geniculate ganglion, which varied from obvious zoster vesicles to small areas of scabbing which, at the time of examination, could not clinically have been diagnosed with certainty as zoster, but which were suggestive of it. All of them gave positive zoster complement-fixation reactions (Table I.) in their serum, and in all it seems reasonable to attribute the facial palsy to an infection of the geniculate ganglion with zoster virus. More or less pain was associated with the onset in six of them, absent in three. In four recovery of muscular power took place in a few weeks; in one it was incomplete after 14 months; in the others its date was not ascertained. In four there was evidence of impairment of taste; in two taste was unimpaired;

in three there is no definite information. In general, therefore, the clinical features of the facial paralysis itself do not differ from those of the familiar Bell's palsy of unascertained origin.

TABLE I

Sera.	Antigens.		Saline.	Sera.	Antigens.		Saline.
	Zoster vesicle fluid.	Derm. herp. vesicle fluid.			Zoster vesicle fluid.	Derm. herp. vesicle fluid.	
Case.	+ 2 M.H.D. complement.			Case.	+ 2 M.H.D. complement.		
1	+ + + + + + + ±	± −	− −	6	+ + + + + + + +	+ + −	± −
2	+ + + +	−	−	7	+ + + + + + + ±	− −	− −
3	+ + + + + + + +	+ + + −	− −	8	+ + + + + + ±	− −	− −
4 *	+ + + +	+ + + +	−	9	+ + + + + +	− −	− −
5	+ + + + + + +	− −	− −				

Derm. herp. = Dermatitis herpetiformis.

The degree of fixation of complement (2 M.H.D.) is indicated by the signs, + + + + representing complete fixation. Where two rows of signs are given, the upper is the reading after 30 minutes at 37°, and the lower is the reading after 24 hours at 0° C. (approx.). The other controls not shown in the Table were uniformly negative.

* In this case the control antigen was strongly anticomplementary, but complete fixation with zoster was also given when 3 M.H.D. and 5 M.H.D. of complement were used; the result has therefore been regarded as positive.

CASES WITHOUT CUTANEOUS ERUPTION

Group II.—Twenty-two cases of facial palsy with no clinical evidence of cutaneous eruption in the neighbourhood of the ear. These were of the familiar clinical type and need not all be recorded in detail. Eruptions of the kind found in the first group were absent, with two doubtful exceptions; in one of these a pustule (not a blister) occurred behind the ear and a "sore place with a whitish centre" on the tongue, two days before the paralysis; in the other the patient noticed one or two small blisters on the outer part of his forehead a week after the occurrence of the paralysis. Fourteen of the patients were women, eight men, and their ages varied from 13 to 60. Ten had associated pain, usually in the ear or mastoid region, sometimes in the neck or along the lower jaw; seven gave definite evidence of disturbance of taste. In 14 recovery was known to have occurred within two months; in three, very little improvement could be detected after two months, but two of these recovered in six months; in the rest information is lacking.

In 18 of these cases (including the two with doubtful eruptions) serum obtained between 9 and 30 days after the appearance of the paralysis gave no zoster complement fixation, and infection with zoster virus would therefore seem to be an unlikely cause of the paralysis.

In the remaining four positive zoster complement fixations were obtained. The clinical details are as follows:—

CASE 10.—A young man, aged 19, who had never had shingles and could not remember chicken-pox, developed a left facial paralysis without pain or other symptom. It had improved considerably by the time he was examined, seven days later, and disappeared in a month. Taste was not affected. A partially positive complement fixation was obtained in serum taken two months after the onset.

CASE 11.—A woman, aged 44, who had never had chicken-pox or shingles, complained of slight bilateral earache for three days, and then developed right facial paralysis. Syringing the ears removed much wax, chiefly from the left. Aching persisted in the right ear, spreading down the neck, for several days longer. Taste was impaired on the right side of the tongue. Serum obtained four days after the onset of the paralysis gave a positive zoster complement fixation. Recovery was gradual.

CASE 12.—A woman, aged 47, who had had chicken-pox in childhood, but never shingles, after two days' severe headache (not earache) of a kind from which she often suffered, developed a right facial paralysis, with a slight sore-throat. Taste was not affected. Serum obtained 15 days later gave a partially positive zoster complement fixation. Recovery took two months.

CASE 13.—A woman, aged 56, who had never had chicken-pox or shingles, suddenly developed a complete left facial paralysis, with some subsequent aching in front of the ear. Taste was unimpaired. Serum obtained 21 days later gave a positive zoster complement fixation. Recovery had not begun in two months.

Clinically, these four cases differ in no characteristic way from the rest of the group. The positive zoster complement fixations (see Table II.) strongly suggest a zoster infection as the cause of the paralysis. There was no history and no sign of any skin eruption in, on, or near the ear, nor of an eruption on the tongue, but the possibility of an eruption confined to the deeper parts of the external auditory meatus was not excluded.

12	+ + + ± + + ±	− −	− −
13	+ + + + + + + ±	− −	− −

For explanation of the signs see Table I.

The 22 cases of this whole group were random cases of Bell's palsy, without cutaneous eruption suggestive of zoster. The serological investigation shows that zoster virus is a possible or probable causative agent in a relatively small proportion of such cases. That proportion is approximately 18 per cent. in this short series, but we have excluded from it 14 other negative cases, otherwise admissible, for the reason that their sera were examined between three and nine days after the appearance of the palsy; antibodies may develop within that period, but their absence in a given case cannot be considered reasonably certain unless the examination is made after the ninth day. We feel, therefore, that a longer series of cases might possibly show an incidence of zoster infection lower than 18 per cent., rather than higher.

Many of the cases in Group I., with cutaneous eruptions, were specially referred to us (Nos. 1 and 3 from Maida Vale Hospital by Dr. Blake Pritchard, to whom we are much indebted); hence the percentage of cases presenting the Ramsay Hunt syndrome in our series has therefore no bearing on the true incidence of such cases in an unselected group of patients with Bell's palsy.

SUMMARY

1. The sera of nine cases of Bell's palsy with zoster-like eruptions in the areas of sensory supply of the geniculate ganglion have been found to contain antibodies to zoster virus, demonstrable by complement

fixation. This is serological evidence supporting Ramsay Hunt's clinical explanation of such cases as due to specific zoster infection of the geniculate ganglion.

2. The sera of 22 cases of Bell's palsy without zoster-like eruptions have been found to contain zoster antibodies in only four instances. Our evidence thus suggests that the majority of such cases are not due to an infection with zoster virus.

We wish to acknowledge with gratitude a great deal of help and advice given us by Dr. S. P. Bedson, of the Freedom Research Laboratory in the London Hospital. One of us (R. T. B.) was assisted by a grant from the Yarrow Research Funds.

Clinical and Laboratory Notes

A STAINING METHOD FOR THE DIRECT TYPING OF PNEUMOCOCCI

BY F. C. O. VALENTINE, M.B. CAMB., M.R.C.P. LOND.

ASSISTANT DIRECTOR OF THE HALE CLINICAL LABORATORIES, LONDON HOSPITAL

AN important advance in the serum treatment of lobar pneumonia was made when Armstrong[1, 2] and Logan and Smeall[3] in simultaneous papers showed that the direct typing of pneumococci in sputum was possible. However it is not always easy, at least for the unpractised eye, to recognise the unstained swollen capsules on which their method depends.

The object of the present communication is to point out that the "neutralised" capsule can be stained by ordinary dyes. The following technique is simple and reasonably quick.

Three or four loopfuls of Type I. serum are mixed on a slide with a fair-sized loopful of sputum and mounted with a cover-glass. The edges of the cover-glass are sealed with vaseline, so that it will not become stuck to the slide. Similar preparations are made with Types II. and III. sera. It is essential that complete neutralisation of the capsule should be obtained, and to ensure this the preparations should be left for 20 to 30 minutes. After this the cover-slips are slid off and discarded. The films left on the slides are allowed to dry and the bulk of the vaseline is scraped off with a knife. The vaseline remaining will not interfere with the staining and blotting of the slides, and it may finally be removed by warming until it is just melted and washing over with xylol. Before staining wash the film under the tap to remove the serum, stain for 2 to 3 minutes with dilute carbol fuchsin, wash and counter-stain for 10 seconds with carbol thionin; wash and blot dry.

It will be found that the bodies of all bacteria stain practically black, and that everything else is red. The capsules of pneumococci treated with the homologous serum appear quite large and stain a strong red, whereas the "unneutralised" capsule does not stain.

The dilute carbol fuchsin used has been filtered Ziehl-Neelsen stain freshly diluted in a test-tube with five or six parts of water. The carbol thionin contains nine parts 5 per cent. phenol in water and one part 50 per cent. alcohol saturated with thionin. In a new bottle this stain usually precipitates, but once the bottle is lined with deposit it lasts well. Saffranin may be used in place of carbol fuchsin, but the capsules are then less intensely stained. Tap-water may be used for washing slides throughout.

Similar methods are very successful in typing the pneumococci in pus, but in this case a few cocci may be seen with lightly stained capsules in mixtures with the heterologous sera. This is probably due to the fact that the patient has had time to produce some antibodies, but it does not appear likely to cause confusion.

When pneumococci cannot be found in sputum and mouse inoculation is inconvenient, a serum agar slope may be inoculated with a good loopful of sputum and the culture washed off in a little saline next day. The presence of a few pneumococci may be gauged by making a film from a loopful of the suspension mixed with a loopful of normal serum, and staining with carbol thionin or other stain capable of fixing the serum. Capsules will show as an unstained halo round the cocci. Unstained zones can, of course, occur in such a film round other bacteria owing to retraction, but a very little experience will enable the pneumococci to be identified. If they are present, equal volumes of suspension and of the type sera may be mixed and sealed in capillary pipettes. Films are made after about 15 minutes, washed and stained as for sputum. Capsules from cultures are considerably narrower than those from sputum or pus but are quite recognisable. It must, of course, be recognised that such a method is inferior to mouse inoculation, both in disclosing the presence of very small numbers of cocci and also in providing no test of virulence.

Where large numbers of pneumococci are present, as in pure cultures or in the peritoneal exudate of mice, it is only necessary to spread films of the organisms in loopfuls of the type sera and stain with carbol thionin. With homologous serum massive agglutination takes place, usually visible to the naked eye.

Capsular staining, although unmistakably present in the agglutinated cocci, is usually less striking than in sputum owing to incomplete "neutralisation" and insufficient antibody, but the agglutination alone will readily identify the type. This latter reaction has been previously described by Sabin,[4] who obtained no capsule staining.

MYELOID LEUKÆMIA TREATED WITH THE FOUR-GRAMME RADIUM BOMB

BY G. WHITE PHILLIPS, M.B. LIVERP., D.M.R.E., L.D.S.

RESIDENT MEDICAL OFFICER, WESTMINSTER HOSPITAL ANNEXE

THE treatment of leukæmia by radiation is now firmly established. No case is cured; it is open to question whether life is prolonged at all. The superiority of radiotherapy over all other forms of treatment is that it can produce in these patients a temporary return to apparent health.

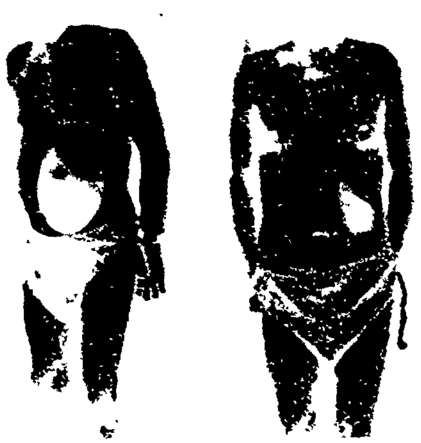
The cause of this condition is unknown, although several theories of its origin have been advanced from time to time. At the moment the balance of opinion seems to be divided between an inflammatory condition of the hæmopoietic system and a neoplastic one. Very little is known of the way in which X rays or the gamma rays of radium produce their biological effects. The treatment of a case of leukæmia by radiation therapy is, therefore, so far entirely empirical.

The case described here is one of myeloid leukæmia treated with a mass of 4 g. of radium. The spleen was the only part of the hæmopoietic system treated, and the reduction in the size of the spleen and in the number of the white blood corpuscles was taken as a guide to the response of the condition to treatment.

CASE RECORD

History.—The patient, a man aged 60, gave a history of having had "rheumatism" for several years, and a *B. coli* infection of the urinary tract in 1927. In June, 1929, he had had sciatica on the right side, treated by injection without relief. His teeth had been examined but were not extracted. In March, 1930, he consulted a doctor in Nice on the grounds of failing general health. Medical examination revealed a greatly enlarged spleen, and a blood count at the time showed the following :—

FIG. 1 FIG. 2



Photographs showing reduction in size of spleen after a week's treatment.

Red cells	3,286,000	Polymorph (neutro.)	69%
White cells	195,000	„ (eosino.)	8%
Hæmoglobin	90%	„ (baso.)	2%
Colour-index	1·3	Myelocytes (neutro.)	20%

He was advised to go to Paris for radiological treatment, but refused. In September, 1930, he was examined in England; the French findings were confirmed. At this time he complained of being easily tired, was constipated, had an indifferent appetite, and became short of breath on slight exertion. He was, however, well enough to play golf.

On examination in October, 1930, his general condition was good, the tongue clean, and the teeth showed slight sepsis. The chest was clear, the heart sound and the blood pressure 130/90. The spleen was very enlarged, extending inwards to the umbilicus and downwards to the iliac crest. The surface of the spleen was smooth and the notch easily palpable.

FIRST COURSE OF TREATMENT

On Oct. 16th, 1930, treatment of the spleen with a mass of 4 g. of radium was commenced. The radium consisted of 20 tubes of 200 mg. each, arranged in a horizontal circle; the radium-skin distance was 9 cm. The total filtration was equivalent to 1 mm. platinum, and the port of entry was a circle 15 cm. in diameter. The spleen was irradiated from the front and back, an exposure of two hours daily being given for seven days, giving in all a total dose of 56,000 mg. hours. Blood counts were done daily. The number of the white cells was reduced after seven days of treatment from 338,000 to 61,000, corresponding to a drop of over 30,000 white corpuscles per day. The white cells continued to decrease for some time after the cessation of treatment.

At the end of treatment the general condition was very definitely improved. The patient felt well, his breathlessness had cleared, and he was very markedly less easily tired. This improvement had occurred without any obvious improvement in either the red cell count or the hæmoglobin index. The reduction in the size of the spleen had been considerable, as is well shown in the photographs taken on Oct. 17th and on Oct. 25th, the day on which the patient left hospital (Figs. 1 and 2).

SECOND COURSE OF TREATMENT

Six months later, on May 5th, 1931, another blood count was done and this showed: hæmoglobin, 86 per cent.; colour-index, 0·6; red cells, 5,580,000; and white cells, 186,000.

Generally his condition was very good, and he was able to pursue his usual activities. The spleen had become enlarged to its previous size. Distance radiation with 4 g. of radium was again instituted, treatment being commenced on June 10th, 1931. The spleen was irradiated on this occasion from the front only, the same apparatus and a radium-skin distance of 9 cm. again being used. He received exposures of only one hour on each of the following days, June 10th, 12th, 15th, 22nd, and 24th, giving a total dose of 20,000 mg. hrs. The result was a very considerable drop in the white cell count.

During this period some interesting observations were made. On June 22nd leucocyte counts were done immediately before and after an hour's application of the bomb. The results are given below. A drop of just over 20,000 had been obtained after one hour's exposure. A repetition of this two days later indicated a similar reduction.

June 22nd

2.50 P.M.		3.50 P.M.	
White cells	92,000	White cells	66,000
Polymorphs—		Polymorphs—	
Neutrophil	72·5%	Neutrophil	61·5%
Eosinophil	1·0%	Eosinophil	1·0%
Basophil	5·0%	Basophil	9·0%
Myelocytes—		Myelocytes—	
Neutrophil	13·5%	Neutrophil	25·5%
		Eosinophil	2·5%
Lymphocytes	0·5%	Lymphocytes	0·5%

June 24th

2.50 P.M.		3.50 P.M.	
White cells	91,000	White cells	70,000
Polymorphs—		Polymorphs—	
Neutrophil	83%	Neutrophil	83%
Eosinophil	0·5%	Eosinophil	1%
Basophil	2·0%	Basophil	1%
Myelocytes—		Myelocytes—	
Neutrophil	12%	Neutrophil	13%
Lymphocytes	1·5%	Lymphocytes	2%

Radiation was stopped on June 24th, when the leucocytes had decreased from 170,000 to 91,000. The spleen had again been reduced in size, being now scarcely palpable. The drop in the leucocytes continued for some days after the treatment was stopped.

THIRD COURSE OF TREATMENT

The patient was seen again four months later, on Oct. 20th, 1931. The clinical picture was similar to that present at the commencement of treatment: shortness of breath on exertion, fatigue, and a greatly enlarged spleen. At this time, however, there was some deterioration in his general condition; he was obviously not as fit a man as he had hitherto been. He himself affirmed that he did not feel really worse, and was able to lead quite a normally useful life. A blood count taken at this time was as follows :—

Red cells	4,370,000	Polymorph (neutro.)	58%
White cells	257,000	„ (eosino.)	1%
Hæmoglobin	66%	Myelocytes (neutro.)	30%
Colour-index	0·7	Myeloblasts	10%
		Lymphocytes	1%

He was readmitted to Westminster Hospital Annexe on Nov. 11th, 1931, and distance radium radiation was commenced on the next day. Employing again the same apparatus at a radium-skin distance of 9 cm., exposures of one hour's duration were given daily to the spleen from the front, for a period of eight days, corresponding to a dose of 32,000 mg. hrs., followed later by four further treatments of one hour each at weekly intervals. After irradiation the leucocytes dropped to 35,000, and the drop continued after the end of treatment to 17,000 on Jan. 7th, 1932. There was also a very marked improvement in the red cell count and hæmoglobin, the red cells rising from 3,870,000 on Dec. 12th, 1931, to 6,120,000 on Jan. 7th, 1932. His general condition was good, and the spleen, previously much enlarged, was no longer palpable. Three weeks later, on Jan. 28th, his general condition was very good, and the spleen was still not palpable. A blood count at this time showed the total number of leucocytes to be 26,000.

On March 17th the patient was in excellent health. He looked well and felt well, and stated that he was able to play a considerable amount of golf with no discomfort. The spleen was still not palpable. A blood count done at the time, however, showed a leucocytic rise: hæmoglobin, 84 per cent.; red blood corpuscles, 5,000,000; white cells, 123,000.

When seen on March 30th he complained of fatigue and shortness of breath, and his general condition was again deteriorating. The spleen was just palpable and the leucocytic count was 123,000. The spleen was again irradiated with 4 g. of radium from the front. He was given an exposure of one hour daily for three days. The leucocytes on April 4th were 103,000, and on April 12th 105,000. The spleen, however, was not palpable. He was given three more hours' irradiation.

The patient returned to Australia in May, 1932. Owing to lack of radium, further radium treatment was not possible. On his return he received deep X ray therapy to the spleen, and his leucocytes dropped from 170,000 to 19,000 without undue shock. The patient stated that he was feeling better then than he had been for the last three years. In August, 1932, he apparently developed phlebitis in both legs, which was reported to be improving; also marked dental sepsis was being attended to.

The chief point of interest about this case is that the patient was treated, up to the time of his return to Australia, by means of distance mass radiation with 4 g. of radium. Cases treated by the surface application of radium have been described, but I have found no record of a case of splenomedullary leukæmia treated by a "bomb."

I wish to acknowledge my indebtedness to Mr. Stanford Cade for allowing me to publish this case.

THE OCCURRENCE OF GOUT DURING THE TREATMENT OF PERNICIOUS ANÆMIA

By W. Gordon Sears, M.D., M.R.C.P. Lond.
SENIOR ASSISTANT MEDICAL OFFICER, MILE END HOSPITAL

THE following case is of interest in view of the fact that it has been shown by Riddle[1] that the level of the blood uric acid rises in pernicious anæmia 24 hours after treatment with liver extract has been commenced, and reaches a maximum just before the peak of the reticulocyte crisis.

Further, Spence,[2] in discussing the effects of treatment in 20 cases, stated that harm may result from taking too much liver after the stage of cure has been reached. He mentioned three instances in which patients had taken 1 lb. of liver daily for three months after the blood-cells had reached their normal level; two of these patients developed acute gout; the third, venous thrombosis with œdema of both legs.

I have not been able to find any other references to the development of gout in pernicious anæmia, although Davidson and Gulland[3] mention its occurrence.

CASE RECORD

A man, aged 49, was admitted to Mile End Hospital on May 4th, 1932. For several months before admission he had complained of shortness of breath and loss of weight. Three weeks previous to admission he had some dental extractions which aggravated the condition.

Previous history.—Gun-shot wound of the left arm and gassed during the war. No history of any serious illnesses.

Examination.—Moderate physique, but evidence of some loss of weight. There was general pallor of the mucous membranes with a lemon-yellow tint of the skin. Slight icterus was evident in the conjunctivæ. Heart: rate regular, not enlarged, no bruits, but sounds rather distant. Alimentary system: edentulous; tongue smooth, but no symptoms of glossitis; lower edge of liver just palpable; spleen not felt. Central nervous system: no abnormal physical signs detected.

A *fractional test-meal* showed achylia gastrica (no neutral red secreted). *Radiography* of the stomach and duodenum showed nothing abnormal. In the stools no occult blood was found.

A blood count gave the following results:—

Hæmoglobin ..	31%	Polymorphs	47%
Red cells	1,650,000	Small lymphocytes ..	32%
White cells ..	6,800	Large lymphocytes ..	17%
Colour-index ..	0·94	Hyalines	4%
Reticulocytes ..	6 per 1000 red cells.		

Red cells showed marked anisocytosis, poikilocytosis, polychromasia, and punctate basophilia. A few nucleated red cells were present. The cells appeared to be of a macrocytic type.

Subsequent progress.—The patient was given ventriculin, four doses daily (40 g.) for five days; the dose was then reduced to 30 g. daily. A marked reticulocyte response was obtained which began on the fourth day and reached its maximum on the sixth day, when the reticulocytes numbered 114 per 1000 red cells. The hæmoglobin rose slowly but steadily, and the red cells after a preliminary drop of 600,000 increased from 1,650,000 to 3,300,000 per c.mm. in 65 days. On the sixteenth day of treatment ½ lb. of liver was added to the diet.

On the thirty-sixth day after liver treatment had commenced he had an attack of gout which affected the metatarso-phalangeal joint of the left great toe and was characterised by pain, swelling, and redness of the joint, lasting three to four days, and then subsiding without leaving any evidence of the lesion. There was no previous history of gout nor any evidence of a gouty diathesis. The arteries appeared healthy and no tophi could be found. Estimations of the uric acid in the blood and urine were not made at this time. Two months after the attack of gout, however, the blood uric acid was found to be raised slightly to 5 mg. per 100 c.cm.

The patient continued to make good progress. The lemon-yellow colour of the skin disappeared, and the icterus of the conjunctivæ was lost. Liver treatment was discontinued on July 18th, having been taken for eight weeks, and Marmite, 6 g. daily, was then given in addition to 20 g. of ventriculin.

I am indebted to Dr. Alan Randle, medical superintendent of Mile End Hospital, for permission to publish this case.

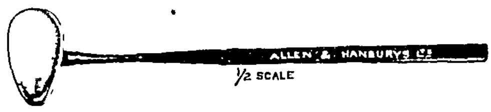
NEW INVENTIONS

A POCKET PERCUSSOR

THE neat percussor shown in the illustration can be carried in the waistcoat pocket. It measures exactly 5 in. long and has a nickel plated metal acorn-shaped head 1 in. long by ½ in. broad at its middle. One end of the acorn is rather more rounded than the other. The handle is of whalebone with tapering butt. Although light, the weight of the head alone is sufficient in use. Most percussors are too large and clumsy and not readily available when most needed. Their large size and rubber attachments rather invite roughness in use.



The instrument is made by Messrs. Allen and Hanburys, Bethnal Green, London, E.

S. WATSON SMITH, M.D., F.R.C.P. Edin.

REVIEWS AND NOTICES OF BOOKS

A System of Surgery

Third edition. Edited by C. C. CHOYCE, C.M.G., C.B.E., B.Sc., M.D., F.R.C.S., *Professor of Surgery, University of London, Surgeon to University College Hospital.* Pathological Editor: J. MARTIN BEATTIE, M.A., M.D., C.M., M.R.C.S., Professor of Bacteriology, University of Liverpool. London: Cassell and Co., Ltd. Three volumes. 1932. Pp. 3330. £6.

Choyce's surgery was recognised as a magnificent achievement from the day of its publication. It reflected all that was good in English and foreign practice, it omitted nothing of any account, it maintained a uniformly high standard, and some of its articles indeed were the finest of their kind in the English language. It was, moreover, excellently printed and illustrated. It seemed almost impossible that future editions should keep to this high level of accomplishment; yet this has been achieved. Some of the original contributors are unfortunately no longer alive, while others are now taking a less active part in surgery, so that the services of new writers had to be enlisted. The editor has chosen these with discretion, and under his supervision the added matter has been welded into the whole. It is impossible to review each section in detail. All the original contributors who have undertaken the work of revision seem to have done it well. Attention therefore is directed to the articles by new authors.

Dr. G. E. Birkett's article on radium is well considered and balanced, emphasising as it does the accurately known facts of radiotherapy. It is sad to reflect that future editions will not have the assistance of this brilliant worker. The subject of radium and X ray burns is well treated by a new contributor, Mr. A. J. Gardham, who writes also of burns in general, giving a good account of modern treatment. Mr. J. B. Hunter has ably revised the chapter on the clinical course and treatment of inflammation. Venereal diseases other than syphilis are described by Mr. A. H. Harkness, obviously from a large experience. The account of gonorrhœal arthritis, however, is not adequate, for to acute arthritis only three and a half lines, to hydrarthrosis two and a half lines, and to polyarthritis one and a half lines are devoted. In the notice of acute epididymitis the views of surgeons who believe in puncture or incision are not mentioned. The author has probably found no advantage to be derived from them. We note also his belief that there is no place in the treatment of these diseases for vesiculotomy, vasostomy, or catheterisation of the common ejaculatory ducts. This article is marred by such sentences as "the best treatment of this condition is to avoid it" (p. 809) and "a diagnosis of prostatitis is seldom wrong if during a course of irrigations the urine passed into both glasses is muddy" (p. 791), where the meaning is rather obscure.

Prof. A. K. Henry contributes an excellent article on surgical diseases caused by animal parasites. We were unaware that the British weever fish may cause so much pain by its sting that its victim has leapt overboard in his agony, and that this pain can be immediately relieved by an injection of potassium permanganate. Local anæsthesia is described by Mr. H. N. Webber, who also writes on spinal anæsthesia. Both these articles are thoroughly up-to-date, but we regret to see the large bore Barker needle still advocated for puncture of the dura. Apparently the author has no objection to a combination of general and spinal anæsthesia, a procedure which would seem to put a very serious strain on the resources of a patient.

In Volume II. Prof. D. P. D. Wilkie has revised the article on diseases of the tongue. The account of lingual cancer is made valuable by the considered judgment on the use of radium. It is well to be reminded that there are some types and situations where the knife is still to be preferred. The author gives rather a scrappy account of the removal of glands on page 125, and the reader might think from his description that the internal jugular vein should be removed on both sides. In one place there seems to be a mistake in the dose of radium for sarcoma. We do not think it sufficiently emphasised that the essential step in the successful removal of a thyroglossal cyst is the excision of a portion of the body of the hyoid bone. It is only suggested that division of the hyoid may be necessary for access. This article would be more useful if formulæ for the paints, ointments, and solutions recommended in treatment were more regularly supplied. It is of interest to learn that radium tends to make leukoplakia worse after an occasional temporary improvement. Mr. H. S. Souttar's contribution on the œsophagus is well planned and balanced. He is not sanguine as to the prospect for surgery in carcinoma of the œsophagus, though due notice is taken of the rare successes of excision. The difficulties of radium treatment are fairly expounded.

The splendid article on the stomach originally contributed by James Sherren has been revised by Mr. A. J. Walton. Sherren's article was above all an account of personal experiences to which it owed so much of its attraction and value. Mr. Walton has tried to maintain its character, but has not been quite successful; he would have been better advised to rewrite the whole article from his own extensive experience. The cauterisation of an adherent chronic gastric ulcer combined with gastro-jejunostomy (p. 251) is a recommendation which few, if any, surgeons follow. Nor do we think in operating upon a perforated gastric ulcer many search for disease of the gall-bladder and appendix (p. 256), whilst it is curious to read that "when the ulcer which has perforated is a chronic one, if the condition of the patient will permit it should be treated as ulcer without this complication." Does the author really mean that he advises a partial gastrectomy? It seems likely that he does, for the matter is referred to again rather obscurely under "ultimate prognosis" on page 257. The statement that duodenal ulcer is most commonly situated on the anterior wall of the first part of the duodenum is still adhered to, although it is contrary to the experience of pathological anatomists in the post-mortem room and to that of surgeons who expose the pancreatic wall of the duodenum in their operations. Modern statistics do not support the claim on p. 263 that at least 90 per cent. of cases of duodenal ulcer can be cured by gastro-jejunostomy. Even if they were only mentioned to be condemned, the experiences of von Eiselsberg, Finsterer, Clairmont, and other continental surgeons in resection operations for duodenal ulcer might fairly be looked for in a textbook of these dimensions. The treatment of gastrojejunal ulcer is rather inadequately described; we read that "this should be preventive," a misuse of words, and "the whole abdominal cavity should be investigated and any other disease there present dealt with." It would be interesting to hear what other disease in the abdomen causes a gastro-jejunal ulcer.

The section on the intestines has been revised by Mr. K. Paterson Brown, who has ably maintained the standard of the original article. The account of intestinal obstruction is one of the best chapters in the book, and is beautifully illustrated. Since the last edition the importance of chloride therapy in this condition has become clear. Alkalæmia is indeed mentioned as one of the adverse factors in obstruction on page 357, but under treatment, later on, we are not told how to combat it. On page 400 we are informed that in post-operative obstruction abdominal pain and colic are seldom complained of. If the author is thinking only of paralytic ileus this may be true, but the statement as it stands is certainly not. Ileo-sigmoidostomy recommended for colitis has been abandoned, and rightly so. It is a little disappointing that in the otherwise excellent account of carcinoma of the colon only 36 lines are devoted to surgical treatment. This section could have been expanded with benefit.

Mr. B. W. Williams now takes part in the chapters on the appendix and peritoneum. Belonging to a school where the delayed treatment is practised, it is not surprising that he gives a good account of this, and categorically states that the difficulties and complications directly attributable to the operative interference outweigh those of the disease. His case is weakened, however, by the subsequent admission that some cases demand operation owing to spreading peritonitis, and that none can foretell what the course of any individual case will be. The statement made on page 446 that it should not be necessary to open a pelvic abscess through the rectum or vagina surprises us. Murphy's method of proctoclysis is not quite correctly described on p. 473; 1 to 2 feet head of water is too great a pressure to use. Murphy insisted on only a few inches to avoid soiling of the bed, and to allow of the expulsion of flatus. Many surgeons find that water is much better than saline solution, which leads to the introduction of too much chloride.

In Vol. III. Mr. Geoffrey Jefferson has written the chapter on peripheral nerves—providing a straightforward modern account of this difficult branch of surgery. Mr. W. Trotter's article on the scalp, skull, and brain remains, under the revision of Mr. Julian Taylor, one of the best to be found anywhere. We note that injection of the Gasserian ganglion is not regarded here as successful as other reports would indicate. We could find no account of the technique of ventriculography or of the increasing use of diathermy in cerebral surgery in recent years. Mr. Taylor also coöperates in the chapter on the spine with happy results.

It requires careful and close reading of this text-book to reveal the passages which might be improved, whilst there is abundant and obvious occasion for praise. Prof. Choyce deserves warm congratulation upon the manner in which he has carried out a task of immense magnitude.

Synthetic Anatomy

By J. E. CHEESMAN, Deputy Medical Officer of Health for Leyton. London: Baillière, Tindall and Cox. 1932. 156 plates. 42*s*.

Dr. Cheesman's ingenious work is now complete. Many students and others who have derived help from the study of these transparent drawings will be pleased to have the full number in their possession. They are intended to supplement, not to supplant, orthodox methods of teaching anatomy, and are admirably planned to serve this end. Part X., the Brain, the last to appear, is sponsored in a foreword by Dr. G. W. B. James, while Prof. J. E. Frazer has contributed an introductory note to the whole series. There can be no doubt that many, in this and in other countries, to whom the descriptive anatomical structure of the body was little more than one of the painful necessities of a medical education, have been led by the examination of these plates to a better way of thinking. The clearness and accuracy of the drawings of the successive layers have had much to do with this result. The author and the publishers are to be congratulated on the completion of this work.

Diseases of the Blood

Second edition. By A. PINEY, M.D., M.R.C.P., M.R.C.S., Director of the Pathological Department, the Cancer Hospital, London. London: J. and A. Churchill. 1932. Pp. 310. 18*s*.

Dr. Piney prefaces the second edition of his book on diseases of the blood with the statement that he only puts forward such views as are commonly accepted. Perhaps as one of those hæmatological enthusiasts he describes as gazing through "charmed magic casements, opening on the foam of perilous seas, in fairy lands forlorn," he has not had the opportunity to keep pace with the more mundane observations of clinical workers. Certainly it is hard to believe that all his statements will meet with general acceptance. He gives a full account of the development of the cells of the blood followed by an analysis of the ever-growing number of blood diseases. Some conditions, like status lymphaticus, whose very existence is denied by many pathologists, are included without question. The hæmatological and anatomical findings, together with possible treatment, are discussed and in many cases fully illustrated from the author's own case-records.

The definition of Banti's disease as a primary disease of the spleen, without qualification, is a bold assumption. Many observers believe that the splenic enlargement is only secondary to some form of portal obstruction. The typical cells of Gaucher's disease are usually thought to contain a phospholipin; Dr. Piney states, without producing any fresh evidence, that the characteristic content is an albuminous substance. His dogmatic statements about acholuric jaundice are equally surprising. Gänsslen has described a large group of cases with no splenic enlargement, while latent cases may present no anæmia.

Misstatements of fact as regards ætiology and treatment are unfortunate in a book which will appeal to the general practitioner. No mention is made of the remarkable therapeutic value of small and repeated blood transfusions in icterus gravis of the new-born. The anæmia of infancy is not regarded to-day as a physiological anæmia. It has been shown by H. Mackay and other observers to be dependent upon a deficiency of iron and to be readily relieved or prevented by the administration of iron alone. On one page Dr. Piney describes it as physiological and likely to be relieved by iron, on the next as "due not only to an iron deficiency." The literature contains scanty evidence that liver extract alone is helpful in treating post-hæmorrhagic anæmias, either clinical or experimental, while iron in adequate amounts, especially if given in conjunction with whole liver, is a powerful aid in blood regeneration. Dr. Piney advises the administration of liver extract, but omits all mention of iron. He is surely unduly pessimistic when he states that "we are completely ignorant as to the mechanism by which the number of leucocytes in the circulation is regulated." The work of Doan, Parker, and Jackson has not only indicated one factor in this regulating mechanism, but has given us a powerful therapeutic agent in certain disturbances of the mechanism. The use of nucleotide is one of the most interesting advances in recent hæmatology.

The book is pleasantly illustrated with the portraits of men who have contributed much to modern understanding of blood diseases. We hoped to find their teaching on the printed page but were disappointed. The chapters are headed with quotations from the poets—"I can be nothing at all, if it is not critical wholly" should be taken as a warning by readers.

Studien über die Entstehung und den Verlauf der Lungenkrankheiten

Second edition. By N. PH. TENDELOO, Professor der allgemeinen Pathologie und der pathologischen Anatomie, Direktor des Pathologischen Instituts der Reichsuniversität, Leiden. Munich: J. F. Bergmann. Pp. 219.

THIS book is one of a small and select company of text-books of pathology which approach the origin of pulmonary disease primarily from the point of view of physiology and function. Broadly speaking, the work may be divided into three portions—an introductory physiological section, a second section dealing with the morbid anatomy of emphysema, and a third section which occupies the major part of the book, devoted to infectious pulmonary diseases. One of the most important parts of the introductory section is a very full account of the mechanism of respiration looked at from the point of view of a pathologist who is primarily interested in impaired function. Another valuable contribution in this section is the long discussion on the inhalation of dust and the pneumonoconioses. Based largely on the early work of Arnold, this particular section will be read with profit by all whose work demands a special interest in industrial respiratory disease.

The section on infectious pulmonary diseases, after a short introduction on the physical and biochemical aspects of these conditions, is devoted to a long and detailed inquiry into lobar pneumonia, bronchopneumonia, and atypical pulmonary inflammations such as infection of the lung in influenza, psittacosis, the typhoid group of diseases, and in plague. It also deals briefly with rare conditions which are not too easy to define clearly, such as "asthenic or adynamic pneumonia," "nervous pneumonia," "abortive pneumonia." The last portion of this section of the book is devoted to a discussion on pulmonary tuberculosis. Throughout this long section Prof. Tendeloo focuses the attention of the reader on a series of questions which are repeated in italics at the head of each subsection. These deal with such matters as the point of origin of the infectious disease; the way in which it extends; the infective agent; the site of the primary and secondary infection; the influence of the various pathological factors on secondary infection; and the significance of the infection in determining the nature of the tissue change. With slight modifications these questions constitute the framework on which the descriptions and discussions are based. Naturally much more emphasis is laid on the soil than on the seed, the latter being a purely bacteriological matter with which the writer is not so much concerned. There is a good bibliography of the earlier work, but we found a little disappointing the omission of references to the recent work on pulmonary asbestosis and on silicosis. Presumably the author regards primary pulmonary neoplasms as outside the scope of the book.

Nervous Disorder in Infancy and Childhood

By NEILL HOBHOUSE, M.D. Oxf., M.R.C.P. Lond., Physician to Out-patients, Victoria Hospital for Children; Assistant Physician, West End Hospital for Nervous Diseases. London: H. K. Lewis and Co., Ltd. 1932. Pp. 212. 8s. 6*d*.

IN this small book Dr. Hobhouse has provided an excellent survey of ground which lies within the province of both neurologist and pædiatrician, and which is seldom thoroughly explored by either. Without entering more deeply into the pathology of the conditions he describes than is necessary for their clinical appreciation, Dr. Hobhouse presents his subject in a way that cannot fail to interest the practitioner. "Nervous disorder" is used in the widest sense, to include both conditions having a demonstrable organic basis and those lying in the borderland between neurology and psychology. A brief outline is given also of the more important psychoneuroses manifested in childhood, and a final section is devoted to mental arrest and deficiency. The presentation of such controversial matters as the causation of the infantile cerebral palsies is excellent, and the book as a whole is admirably balanced.

Human Cancer

BY ARTHUR PURDIE STOUT, M.D., Associate Professor of Surgery, College of Physicians and Surgeons, Columbia Hospital, N.Y. London: Henry Kimpton. 1932. Pp. 1007. 45s.

THIS elaborate monograph deals with human cancer and human cancer alone. No space is devoted to generalities, and no attempt is made to treat malignant disease as a biological and experimental problem. After the briefest introduction, Dr. Stout describes the disease as it affects various tissues and organs of the body. The scope of the work is indicated by its sub-title, "Etiological Factors; pre-cancerous lesions; growth; spread; diagnosis; prognosis; principles of treatment." Some regions of the body are naturally treated in much greater detail than others. Malignant disease of the mammary gland, for example, is discussed exhaustively, but other regions of the body receive due consideration and the author is to be congratulated on a balanced review of the whole subject. Dr. Stout takes a sane view of the relation which should obtain between the surgeon and the pathologist, and his estimation of the relative importance that should be assigned to clinical and pathological observations in the diagnosis and treatment of malignant disease is to be commended. He gives a word of caution on the modern doctrine that it is possible to determine the degree of malignancy of any particular tumour from its histology; this does not come amiss. The microscopical diagnosis of the degree of malignancy as formulated by Broders is, he holds, of value provided one has an opportunity to study the tumour in general and not just one portion of it, but he emphasises the danger of placing too great reliance on an incomplete histological examination, a warning which is repeated more than once in the book. With his views on the value of the rapid section prepared at the time of the operation we also concur. Such a section may be of great value, but the difficulties and possible fallacies of this method must not be forgotten. One phrase is unfortunate. On page 316, in discussing the value of the microscopic diagnosis of malignant disease, Dr. Stout says: "With care and experience, one can separate the malignant from the non-malignant with a considerable degree of accuracy; certainly with far greater accuracy than by any of the serological and other methods of cancer diagnosis." This is surely an understatement of the contribution morbid histologists have made to clinical medicine.

In his preface the author alludes to silver as a diagnostic stain, and the technique of silver staining is described by Dr. George F. Laidlaw in a short appendix. Hardly enough reference to the value of this method is made in the text to indicate in what way this technique is superior to older ones.

The book is well illustrated and to each chapter is attached an adequate bibliography, the references being arranged according to the year of publication. The work will, we think, be appreciated both by the surgeon and the clinical pathologist.

Précis de cancérologie

By G. Ducuing, Professeur à la Faculté de Médecine, Chirurgien-chef des hôpitaux. Paris: Masson et Cie. 1932. Pp. 1259. Fr.140.

This book, by the director of the cancer clinic in Toulouse, has been written, as Dr. Ducuing explains in his preface, to enable the medical student to find in one volume a statement of the pathological conceptions of cancer and the clinical facts and observations regarding different tumours. The first 250 pages set out the general pathology of cancer including its experimental investigation, and a chapter on treatment follows. The greater part of this chapter is devoted to a fairly detailed account of the principles and practice of radiotherapy. The remaining 900 pages deal with the study of malignant tumours in the different sites. A brief review of the anatomy of the normal structures precedes each section, and the author then gives an account of the ætiology, morbid anatomy and histology, symptoms, prognosis, complications, clinical forms, diagnosis, and treatment of malignant tumours affecting the region. The book is written in a clear and concise style and is illustrated by instructive diagrams. The information conveyed is sound and reliable, and generally, wherever a point is in dispute, this is clearly indicated. But under the heading Contagion the author discusses the evidence of cancer houses, cancer cages, cancer à deux, and after pointing out the unconvincing nature of such evidence concludes nevertheless that "the problem of the contagious nature of cancer has not been solved." The author may have confused here the terms "contagion" and "infection," but in any case it would be a serious mistake to give the medical student the impression that cancer may in any circumstances be a contagious disease.

The book can be recommended to the medical student and the practitioner.

The Causes of Evolution

By J. B. S. Haldane, F.R.S. London: Longmans, Green and Co. 1932. Pp. 234. 7*s.* 6*d.*

These lectures were given to the University of Wales at Aberystwyth, and their purpose is to rehabilitate, in the light of modern knowledge, the Darwinism which many have supposed to be discredited or even dead. They fall into two parts. In the first Prof. Haldane gives an account of the discontinuous variations *per saltus* which have occupied the geneticist so much since the rediscovery of Mendel's work. He describes the various ways in which unit characters can vary either alone or in combination with one another, and draws attention to the fact that the results may on inspection be indistinguishable from a continuous series. Of all this Darwin knew hardly anything, and what little had come to his notice he deliberately put aside. Such variations, in Prof. Haldane's opinion, give material which is adequate to account for new species if it is sifted by means of natural selection. The second part discusses the operation of natural selection in the light of the mathematical work of R. A. Fisher, S. Wright, and Prof. Haldane himself; here for the first time it is attempted to find out what really happens when one form has this or that degree of advantage over another. The mathematics of the appendix in which the details are given may be unintelligible to many people, but the conclusions which emerge are of great interest and obvious importance. In summary, the book argues, interestingly and open-mindedly, that natural selection is the main cause of evolutionary change, though it will not account for the actual steps by which individuals come to differ from their parents. These are due to other, unknown, causes and hence evolution can follow only certain paths.

Microscopic Slide Precipitation Tests

For the Diagnosis and Exclusion of Syphilis. By B. S. Kline, A.B., M.D., Chief of Laboratories, Mount Sinai Hospital, Cleveland, Ohio. London: Baillière, Tindall and Cox. 1932. Pp. 99. 13*s.* 6*d.*

The Kline test is a refinement of the Kahn test, Dr. Kline having originally attempted to overcome the great drawback of this test, which is difficulty in reading, by performing the Kahn test on a slide and reading the results microscopically. Although in 95 per cent. of cases agreement was reached with the clinical condition of the patient, Kline went on to investigate the optimum requirements for antigen preparation, cholesterol, mixing of ingredients, temperature effects, &c. The book contains a good but superficial review of these variations and their effects. The outcome of all this work was the development of the Kline tests for use on heated or unheated serum, cerebro-spinal fluid, or defibrinated blood (which can be taken from the finger). The most important factors in the test are the substitution of the acetone insoluble fraction of alcoholic heart extract (phosphatid) for the ordinary alcoholic ether extract used for other tests, and the use of ringed slides in which the tests are carried out, which allow the results to be read microscopically. The routine test on heated serum is a very simple process which is easy to read, and can be carried out without elaborate apparatus. This, together with the more sensitive method—the exclusion test—should become one of the standard flocculation tests for use in the early sero-diagnosis of syphilis, and as a criterion of complete cure more reliable than the Wassermann reaction.

The book itself is short and is simply written, but the author appears to set himself the task of filling more space than was strictly necessary. This has resulted in some excellently produced full-page photomicrographs showing positive and negative reactions which are quite useful; but it is a pity that the book should have been half filled with puerile pictures illustrating the various stages in the different tests, including repeated drawings of a microscope, test-tubes, centrifuge, and even a collection of animals to indicate when each of these is to be used.

THE LANCET

LONDON: SATURDAY, JANUARY 7, 1933

EFFICIENCY IN MEDICAL PRACTICE

KNOWLEDGE comes but wisdom lingers. In the world at large the outstanding failure of 1932 was a failure to apply the unprecedented power that has come from new knowledge. For the moment what is needed is not so much fresh discoveries—fresh gifts from the gods—as the will and wisdom to apply those we have already. And what is needed by the world at large is needed in most of its constituent activities—including medicine. Speaking of conditions in America Dr. RAY LYMAN WILBUR says: "We now find ourselves with a great mass of usable facts, with a splendid body of trained men and women ready to apply them for the benefit of humanity, but without an administrative or economic system which will give all members of our society an even or an adequate opportunity to profit by them."[1] This country, unlike the United States, has a scheme of national health insurance which does much to keep practitioners in touch with those who require their help and could not otherwise get it. But which of us here is really satisfied with the efficiency of medical service as a whole?

Dr. WILBUR's remark was made in introducing the report of a committee which has been studying for five years the manifold problems presented in providing an efficient medical service. This committee (see p. 47) was impressed by the failure of medical service both in quantity and quality, and by the wastefulness of private practice as at present conducted in the States. Its majority report says that the solution is group practice for group payment. While the personal relation between patient and practitioner must be preserved—and those who like to do so can pay individual fees as at present—the costs of medical care should be provided through insurance or taxation or both, and the service should be given by groups of physicians, dentists, nurses, pharmacists, and other associated personnel. These groups are to be organised, preferably round a hospital, for rendering "complete home, office, and hospital care." While all the basic public health services are to be extended, it is the duty of every State and local community to see that the local machinery is in smooth running order. To quote Dr. WILBUR again:—

> "The more local we can make the conduct of these medical enterprises . . . the better the results are going to be. Those who know the most about the individual are those near at hand, and, if they can make these decisions, we are almost sure to have them reasonably wise. I fear decisions in this field made too far afield by legislative groups with authority and with funds. But I also fear that that is exactly what will happen if the medical profession fails to go at this job and do it well."[1]

What the minority of the committee fear, on the other hand, is the exploitation of doctors by business men, and the further removal of the general practitioner from the central place in medical practice. Government care of "the indigent" is, indeed, to be expanded; but only with the ultimate object of relieving the medical profession of this burden. The minority report, which represents the official view of the American Medical Association, thinks that insurance is the shortest road to the commercialisation of medicine. Wherever voluntary insurance is provided by contract with organised groups of doctors there is (it is stated) solicitation of patients, destructive competition among professional groups, inferior medical service, loss of personal relation of patient and physician, and demoralisation of the profession. Having devoted two long leading articles to dismissal of the majority's proposals, the Association's *Journal* (Dec. 10th) says:—

> "There is, moreover, a far greater concern than the rights of the physician to practise as his knowledge and training indicate is desirable. There is the question of Americanism versus sovietism for the American people. There is the question of the right of the American citizen to pick his own doctor and his own hospital, to pay his own bills with his own money, to be responsible to a doctor who is responsible to him."

This would be more convincing if it were true that all Americans are well off. But in the United States, as in England, there are many people, besides the really poor, who avoid medical care because they cannot pay for it. Why is it better that they should insure themselves with an insurance company (which makes a profit) than with a group of doctors?

In industry the proper place of private and public enterprise is to-day in doubt. So it is in medicine, with the additional complication that here there is a third form of undertaking—the charitable. What sort of equilibrium are these three going to reach? Popular political theory now favours formation of semi-independent public trusts, like the B.B.C., and instead of the long-prophesied State medical service we are perhaps to see a National Medical Corporation, under medical management, providing complete medical care for everybody who buys a licence at a post office. Fashions change, however, and for the moment there is no question of choosing an organisation which shall comprehend and unify every form of medical service. Meanwhile the profession is too wise (or disillusioned) to support or condemn particular schemes because they can be given political labels: the test is, do they work? It is hard to foretell the future, but if we cannot see our objective we can at least examine the methods now in use, detect their faults, and decide which of their features must at all costs be preserved. Economic pressure has done much to prevent the expansion of municipal health services, but in certain localities we shall soon have an example of what can be done in providing medical help for every citizen who needs it. Does this plan work? Economic pressure, again, is altering the ideal of our charitable hospitals; they are turning to systems of contributory insurance for their support, they may even be obliged to pay their visiting medical staffs. Is this the service demanded by our middle classes? How far can the hospitals take up the burden of chronic ill-health which causes so much distress and economic loss to-day? The King's Fund report (noticed on p. 42) rightly concludes that out-patient departments are not fitted to bear this burden—that they should more and more be consultative centres.

---

[1] New Eng. Jour. Med., Dec. 15th, 1932, p. 1073.

If, however, the burden is to be passed back to the general practitioner, his facilities for treatment must be better. The *Journal of the American Medical Association* (Dec. 3rd) says that experience has shown that more than 80 per cent. of all the ailments for which people seek medical aid can be treated most cheaply and most satisfactorily by a family physician with what he can carry in a handbag. This may be true; and like the *J.A.M.A.* we believe that the general practitioner ought to take the central place in medical practice. But we do not believe in family doctors who have no resources, no interests, outside their handbags. We believe that association and coöperation with other practitioners, and preferably with hospitals, will be required for practice in the future. The American scheme of group practice round a hospital, with its reminder of the Dawson report, is one way of achieving this object: the "public medical services" of this country represent another; and a public medical service with hospital and other equipment of its own would approximate to the ideal of Dr. Wilbur's committee. More humble, but none the less important, was the suggestion for "medical houses" put forward by a correspondent in our columns just a year ago.[2] We have yet to hear that anyone has explored the possibilities of this reasonable proposal; yet it is on such experiments, not on social theorising, that the future of medical practice depends. And without efficient medical practice we shall get little good from medical science.

METABOLISM OF THE CANCER CELL

Whilst there is nothing new in the basic idea of chemical differences between normal and malignant cells, it is only in recent years that the existence of definite abnormality in the metabolism of the cancer cell has received experimental proof through the brilliant researches of Otto Warburg. The cancer cell is distinguished above all by its power of rapid and uncontrolled growth. Such growth demands supplies of energy not liberated by hydrolytic reactions or lipase action, so that whilst the study of such processes may yet be of the greatest importance it cannot yield directly the secret of the rapid growth of tumour tissue even in its more limited aspect as a problem in metabolism. If we consider the processes which may yield energy for growth in animal tissues the main source is, of course, the tissue-respiration, and it is therefore at first sight surprising that it is only in very recent years that the oxidative reactions of the cancer cell have received any thorough investigation, though the pioneer experiments of B. R. G. Russell and W. E. Gye were made in 1920. The reason for the apparent neglect is that the study of the respiration and oxidative metabolism of the cancer cell, like many other problems of cell-physiology, has had to await the development of sufficiently refined methods. Now, as H. G. Crabtree points out in a recent review,[1] the whole subject of the chemical reactions occurring in animal cells and supplying their demands for energy which can be utilised for growth and functional activity, has been made accessible to experimental study. Prof. Warburg's work on cancer was a logical development of earlier studies of a purely physiological problem connected with the oxidative changes in the sea-urchin's egg: Warburg found the respiration of the eggs to be enormously increased when the eggs were fertilised. Rapid development was here accompanied by a great increase in cell-respiration, and the question arose whether this was also true of the cells of rapidly proliferating tumour tissue. Methods of great delicacy were evolved in order to put this idea to experimental test; but it was soon clear that no difference in respiration of anything approaching the same order exists between normal and tumour tissues. In fact the amount of oxygen consumed by the two does not differ at all markedly.

These earlier experiments on the metabolism of the cancer cell, though yielding an enigmatic response as far as the respiration was concerned, led Warburg directly to the discovery in 1923 of an alternative energy source possessed by malignant tissue—its extraordinary and previously unsuspected power of lactic acid formation. It is this discovery which has been the direct starting point of all recent work on this subject. Cancer cells differ from the great majority of normal tissue cells in their enormous production of lactic acid; an outpouring which persists even when the cells are freely supplied with all the oxygen of which they can make use. Every hour a quantity of lactic acid equal to a tenth of the dry weight of the tumour tissue is produced; in 48 hours therefore a weight of lactic acid approximately equal to the tumour's own fresh-weight may be poured forth from the malignant tissue. The breakdown of carbohydrate into lactic acid is, as is well known, a process in which considerable energy is set free; in muscular contraction, for example, the energy may be used for the production of mechanical work, whilst the lactic acid bacteria are able to grow and multiply anaerobically at the expense of the same chemical reaction. Thus the tumour cell has at its disposal, besides its respiration, an additional source of energy not dependent for its existence on the oxygen supply of the tumour: for short periods, at any rate, the tumour cell can live under strictly anaerobic conditions, as experiments in Warburg's laboratory have shown, though in order to enable it to do so the tumour must have an adequate supply of sugar for its anaerobic life. Here therefore was a discovery of prime importance, the significance of which is even now not fully realised. So striking is this property of aerobic glycolysis of the cancer cell that it is sometimes forgotten that the respiration is still quantitatively the main source of energy of malignant as of other tissues, accounting on an average for some 70 per cent. of the cells' total energy output. The glycolysis is not to be regarded as an independent entity, unconnected with respiration: and in the last few years attention has been more and more focused on the relationships existing between respiration and lactic acid formation in animal tissues. Nearly all tissues are able to form lactic acid from carbohydrate when their respiration is damaged or suppressed—as. for example, by poisoning with cyanide or by maintaining the tissue in an oxygen-free atmosphere. Embryonic tissues were under these conditions found by Warburg to give rise to amounts of lactic acid which, in the case of very rapidly growing tissues. may equal those formed by the most active tumours. In tumours therefore the respiration has to a large extent lost the property. which it normally possesses in almost all normal tissues, of suppressing the lactic acid formation. Normal tissues, with a very few exceptions. of which the warm-blooded retina is the most striking example, do not form any appreciable quantity of lactic acid under conditions where care is taken that their respiration shall be uninjured, as in the conditions of Warburg's experiments. On the other hand. by a partial asphyxia produced by depriving embryonic tissues of oxygen for a time, or by cyanide poisoning, Warburg was able to show a change of metabolic habit, resulting from the injured respiration, so that in the partially asphyxiated tissue aerobic glycolysis was regularly found, even when the full oxygen supply was restored to the tissue. It is possible that the abnormality of the retina, mentioned above, may be referred to a similar cause on account of the great sensitiveness of this tissue to oxygen deprivation. In any case, it is clear that much more knowledge is urgently needed concerning this damage to respiration in tumour tissue. From measurements of respiratory quotient F. Dickens and F. Simer have concluded that it is the oxidation of carbohydrate that is primarily affected in tumour tissue; for whilst they found the respiratory quotient of rapidly growing embryonic mammalian tissues was almost always unity, indicating normal oxidation of carbohydrate. in tumour tissues the respiratory quotient was always less than unity as measured by the specially devised methods of these authors.

[2] Friel, A. R.: The Out-patient Problem: a Suggested Policy, The Lancet, 1932, i., 55.

[1] Thirtieth Annual Report of the Imperial Cancer Research Fund, November, 1932.

As yet attempts of therapeutic application of Warburg's discoveries have not yielded any very definite results. The ability of the cancer cell to live without respiration provided that it has adequate carbohydrate, or in a medium of low sugar concentration if it is able to respire, militates against therapeutic attack by deprivation methods. It seems clear that our knowledge of the metabolic aspects of the problem have not as yet been carried far enough to enable us to devise means to restore the metabolism of the cancer cell to normal to be made, except upon empirical lines. This is one of the many problems opened up by Prof. Warburg's discoveries.

◆

PSYCHOTHERAPY IN THE CURRICULUM

If it were possible yet to see in proper perspective the trend of medical progress during the year now ended, it seems likely that the penetration of psychological views into general medicine would stand out as its most salient feature. For long this penetration was so slow as to be almost unrecognised, but the acceleration of a change of outlook, which is not confined to this country. has recently been so notable as to betoken the opening of an important phase in medical history. Dr. Gillespie, in a lecture on psychotherapy and general practice which is printed on another page, suggests that since the development of scientific ideals medicine has shown a bias in favour of physical ætiology for every disorder and a persistent disregard of psychological aspects. Some results of this bias are manifest in the case-histories he records. Dr. W. Langdon Brown, in his inaugural lecture as Regius professor in Cambridge,[1] rejoices that in these latter days medicine is becoming increasingly psychological in its approach to disease, while not neglecting the development of its scientific armamentarium. His personal conviction, gained "by sheer force of experience," of the need for a more scientific approach to medicine was forcibly stated in his address at the recent opening of the new home of the Institute of Medical Psychology (see p. 64). No one is likely nowadays to doubt the truth of his contention that quite as many people are ill because they are unhappy as are unhappy because they are ill. Many general practitioners, who not so long ago were sure of their competence to deal with most of the cases presented to them, are now becoming conscious of the large proportion of their patients who really require mental rather than physical alteratives, and are dissatisfied with their equipment to cope with them. This dissatisfaction was voiced recently at an old students' dinner when the plea for help from the teaching schools received unexpectedly wide support.

The almost complete omission of the subject of psychotherapy from our medical curriculum, has a bearing on the dispute now raging (see p. 54) whether or not a practitioner is entitled to claim a fee for such treatment in respect of his panel patients. The opposition to its inclusion can only be understood when the attitude is viewed in historical perspective. Towards the end of the last century the experiments of Charcot and the more productive efforts of Janet had prepared the way for Freud. whose work offered at least a pathology of those psychoneurotic conditions which, in some guise or other, had always been a puzzle to medicine. Attention was being attracted to this work when the Great War broke out. Then came the shell-shock episode and, in accordance with the mental attitude of the time, there was built up a phantastic pathology, and we decorated hysterical subjects with wound-stripes as a sign of having received physical injury at the hands of the enemy. When the loss of man power attributed to shell-shock forced a recognition of the psychological nature of disorders of this category, qualified medical men were encouraged to take up the study of psychopathology in order to treat the abundant material that cumbered our military hospitals. Then the new theories were, in some form or other, found indispensable to the understanding and treatment of the condition, and the young men thus initiated into the subject became a leaven that encouraged the change of attitude alluded to above. The clash of principles manifest at this time was, however, but a repetition of ancient controversy. Vitalists and mechanists, under various names, have supported their opposing principles throughout the centuries; to the *physis* of Hippocrates, the *anima* of Stahl, the *blas* of Van Helmont, were opposed the atoms of Asclepiades and the ethereal fluid of Hoffmann, and now we may choose between the libido of the psychoanalysts and the glandular predominances of Berman, or build up out of conditioned reflexes a psychology without a psyche. In the eighteenth century arose a pseudo-physiological terminology that has just received a blow from the request, in the Official Nomenclature of Diseases, that the word "neurasthenia" should be avoided. Aided by this terminology, and encouraged by wonderful advances in a material science that counted teleology as heresy, we have regarded animism in any form as dead. If the medical student heard it mentioned it was as an obstructive theory finally overthrown by the synthesis of urea. For him the test-tube and microscope were ultimate authorities. and if a "nervous" disorder had to be labelled "functional" that was only because our methods had not quite reached the perfection that would enable us to understand its mechanism. This fundamental assumption is responsible for the irrelevant pathology that has led to so much mishandling of the psychoneurotic patient. It is the same assumption against which Stahl, a sound clinician, fought in the seventeenth century, when he protested that the anatomy and physiology of his day were given a greater load than they could carry. Unfortunately he departed from a safe agnosticism and propounded a sterile theory of animism which is remembered to his disadvantage, whilst the lesson he sought to teach has been forgotten. Now at last, however, psychopathology is presented to us as a body of observation and theory, adaptable to clinical use and capable of some degree of systematisation, whose advocates find in it nothing contrary to physiological principles. Objections have been made that the newer conception deals with what cannot be weighed or measured, that it departs from the basic principles of cause and effect by introducing the conception of aim, and is therefore unworthy to be granted validity as a science: but this expresses the attitude rather of nineteenth century science than the position in which we stand to-day. The practical psychotherapist tends to ignore such objections, while a study of their origin would enable him to meet them effectively.

---

[1] Cambridge University Press. 1932. Pp. 52. 2s.

The rapid changes now taking place have thus a deep historical significance. Apart from special establishments like the Institute of Medical Psychology which has developed from modest beginnings as the Tavistock Clinic, and organises well-attended courses for practitioners, there are several out-patient departments at general and neurological hospitals, and at some teaching hospitals lectures are given on the psychoneuroses in addition to the old-established tuition in psychiatry. But whether the clinical material present in every department is used for demonstration or whether it is ignored, or even unrecognised, depends upon the personality of the physician or surgeon in charge of the department. There are two main obstacles to the development of special teaching: first, the lack of examination value, for no question on the subject is as yet expected at any qualifying examination; secondly, perhaps a relic of the bias against psycho-analysis, the impression that an interest in this subject is at best morbid and at worst indecent. On the other hand, the growing demand from both practitioners and students for instruction in psychopathology and psychotherapeutics is not likely to be ignored by the committee now considering the curriculum. Any official recognition given to psychotherapy, whatever its extent, should have beneficial results far beyond its immediate outcome, for a new orientation on the part of clinical teachers is at least as important as the organisation of specific instruction.

THE SEX HORMONES

IN many branches of medical research knowledge is developing so rapidly that the practitioner must rely upon well-informed reviews in order to keep up to date. Particularly does this apply to the mechanism of the internal secretions, and most of all to those connected with the regulation of the sexual cycle. Any person attempting to keep up with the world literature on this subject would have to devote his full time to reading, and even then it is doubtful if he would succeed in sorting out the wheat from the chaff, when the chaff can so readily be mistaken for wheat. What experienced worker would have believed a few years ago that pregnancy could be diagnosed accurately within the first few weeks of gestation by injecting the patient's urine into immature mice, and later inspecting their entrails in the augural manner? Recent development in this subject is well outlined in the article by Prof. Walther Schoeller, which appears later in this issue. He emphasises the great importance of a possible relationship between plant and animal hormones, and to many medical readers it may come as a surprise to learn that plants have hormones. The review indicates the complexity of the subject, and the large number of experimenters at present engaged on the problem. The major part of the pioneer work comes from Germany and America, but important observations have been made in this country without which progress might have stayed. Thus the chemical work of Marrian, referred to by Prof. Schoeller, has proved to be of much significance, and the chemical and physiological studies of Dodds, Parkes, and their co-workers have been another essential link in the chain.

ANNOTATIONS

THE NEW YEAR HONOURS

THE list of honours issued on Jan. 1st contains but a small number of medical men, and is mainly composed, according to what is becoming a regular plan, of those who obtain recognition or advancement in the various Services, militant and civil. Medicine, however, welcomes a new peer, and Sir Thomas Horder will be acclaimed by his fellow-practitioners as a worthy recipient of the high honour. Alike as a great clinical physician, and as a vigorous and acute worker in fields of wide social interest, Sir Thomas has the personality needed for effective membership of the Upper House, and the well-merited distinction will surely receive further justification. Four members of the medical profession receive knighthoods, among them being Major-General Dick Megaw, the Director-General, I.M.S., and Dr. F. J. Willans, surgeon apothecary to H.M. Household at Sandringham. Dr. Charlotte Purnell, who is created O.B.E., is the devoted medical missionary, who has worked for 20 years in Palestine, and is now in charge of the Mission Station in Amman. We note with pleasure the knighthood awarded to Prof. F. T. G. Hobday, the Principal of the Royal Veterinary College, in the interests of which he has worked long and untiringly; and many will appreciate, as we do, how well deserved was the same honour by Principal R. S. Rait, Vice-Chancellor of Glasgow University. Our readers will also approve highly of the bestowal of the C.B.E. on Mrs. Alice Baker, a founder of the Medical Research Institute, Melbourne; Mr. Reginald Blunt, for half a century associated with the Cheyne Hospital for Children; Mr. Peter Evans, an energetic worker in the cause of the blind; and Prof. F. H. A. Marshall, director of the Institute of Animal Nutrition at Cambridge and an authority on sexual physiology. A detailed list of recipients is published on another page, to all of whom we offer congratulations on the public acknowledgment of their merits.

RECTAL OR VAGINAL EXAMINATION IN LABOUR

THE examination of patients by the rectum during labour was recommended by Reis and Kronig in 1893, in the hope that the avoidance of vaginal examination might diminish the incidence of puerperal sepsis. The method has been widely used but has not met with general approval, and it is doubtful whether it has any advantage other than saving the trouble of washing the hands. H. W. Mayes has analysed [1] the results of rectal and vaginal examinations in 3884 cases at the Methodist Episcopal Hospital in Brooklyn. He found that the morbidity-rate among those patients who were examined per vaginam was about 1 per cent. higher than the morbidity-rate of those who were examined only per rectum. In 1947 cases examined by the rectum alone the morbidity-rate was 5·08 per cent. Rectal examination therefore does not abolish the danger of puerperal infection, and the higher rate following vaginal examination is accounted for by the fact that the parturient woman was examined by this route in all cases of difficult or prolonged labour. Of several objections to the routine adoption of rectal examination the most important is its inaccuracy. Dr. Mayes states that a 10 per cent. error is generally admitted for those with experience, and he suggests that the prevailing high stillbirth-rate may be due in part to the fact that abnormal conditions are not recognised in time by rectal examination. The student in fact finds it hard enough to make a diagnosis by vaginal examination and would, one fears, learn nothing if he were to examine his quota of 20 cases by the rectum instead. Before a man is sure of his rectal findings, Dr. Mayes remarks, he must follow at least 100 patients through labour. It should also be borne in mind that the posterior vaginal wall which is forced into the cervix during rectal examination cannot be considered much more sterile than the examiner's finger. Moreover, the rectal mucous membrane may be injured and pathogenic organisms escape into the tissues of the recto-vaginal septum. When the finger is withdrawn the perineum is left contaminated. The question is bound up with that of vaginal antisepsis which is not yet settled. In this country bacteriologists tell us that it is impossible to sterilise the vaginal wall, and most obstetricians think that the introduction of antiseptics into the vagina gives no better results than the customary swabbing of the vulva. Dr. Mayes advises the injection of mercurochrome, and thinks that by its means it is possible to sterilise the vagina. To one holding this view vaginal examination becomes a safe procedure, and he therefore recommends the abandonment of rectal examination during labour.

"THE SOCIAL PROBLEM GROUP"

AT the conference of the Central Association for Mental Welfare held last month in London, Mr. E. J. Lidbetter read a paper upon the Value of Family Histories in the Study of the Inheritance of Mental Defect. For the last 25 years he has been conducting an inquiry into the relation between heredity and social inadequacy in an East London area, his procedure having been to prepare elaborate family pedigrees of persons admitted into the poor-law institution of that area. This investigation has now attained comprehensive proportions, and he was able to show the meeting a few of his charted pedigrees. The following are among the chief conclusions reached: that a conspicuously large number of mentally defective children are born in families containing a record of certifiable insanity; that the families studied have a much larger fertility-rate and, as a result of the improvement of their conditions in recent years, a larger survival-rate than any other social element in the community; and that the principle of assortative mating clearly holds in the families he has studied. This last observation Mr. Lidbetter regards as eugenically encouraging. His evidence suggests that families containing defective, "sub-cultural," and mentally backward persons which, in aggregate, have been referred to by the Wood Committee as comprising the social problem group, are closely intermingled and overlap: and that they preserve their characteristics from generation to generation, and probably do not often, by intermarriage, vitiate good stocks or derive survival strength from out-breeding with such stocks.

Mr. Lidbetter's inquiries, conducted over a long period of years in a restricted urban area, confirm the findings of the much more comprehensive though less intensive survey conducted by Dr. E. O. Lewis and described in the Wood report. These findings raise biological problems of the first importance. To what extent are the various manifestations of social inadequacy evinced by the social problem group the product, on the one hand, of inborn and hereditary factors, or on the other, of such extrinsic influences as are constituted by the insanitary environment of a slum district, the bad family tradition, and subversive parental example which too often exist among them? The remedies adopted by social reformers will clearly depend on the answer to this question. In concluding his address, Mr. Lidbetter stressed the need of a comprehensive and impartial investigation, carried out under proper authority and by competent persons, and planned so as to supplement such local investigations as those now being carried out by Mr. Caradog Jones, of the department of social science at Liverpool University, and the Eugenics Society. The latter has devised a questionnaire which has the object of reversing the procedure followed by Dr. Lewis. The latter, starting from a specific investigation into mental defectiveness, was led to recognise the importance of a social problem group, largely composed of subnormal though not certifiably defective persons, who are the main procreators of mental defectiveness. The inquiry of the Eugenics Society, starting from a special manifestation of social inadequacy—in this case the continuous receipt of poor-law relief for two years or longer—seeks to ascertain whether the incidence of mental defectives in such families is higher than the average familial incidence obtaining in the community at large. It will be difficult to imagine an investigation of greater social importance than that proposed by Mr. Lidbetter. If the conception of a "social problem group" is justified, and if it has the characteristics which have been described, it is clearly a matter of national urgency that the fertility of its constituent members be limited by any reasonable methods that do not involve compulsion or injustice. In view of the high fertility-rate which all observers have noted as characterising the group, it would appear that if measures designed with this end are not soon adopted, seeds may be sown which, several generations hence, will germinate with disastrous social consequences.

THE LIVER IN ECLAMPSIA

DEGENERATION of liver cells is present in all or nearly all fatal cases of eclampsia, though only about half of them show the fibrino-hæmorrhagic necroses which are characteristic of the disease in the sense that they are never seen in its absence. But how the liver changes are produced has never been satisfactorily determined, despite a great deal of investigation, mostly along biochemical lines. Dr. G. W. Theobald,[1] working at University College, now produces an attractively simple mechanical explanation. He thinks that the lesions are due to increased intra-abdominal pressure—i.e., that they are the result rather than the cause of the convulsions. He supports his thesis with some striking experiments on dogs and cats. The animal has its belly tightened up somewhat by the injection of about a litre of bland liquid into the peritoneal cavity. Binders are then placed round the abdomen and drawn tight, by which manœuvre the intra-abdominal pressure is raised to 80–100 cm. of salt solution. Maintained for two minutes, this constitutes an imitation "fit." By this means, severe and extensive necrosis of liver is produced in nearly all animals, and as the liver is sensitive to changes in its blood-supply and autolyses quickly, quite obvious alterations, naked eye and microscopical, are found after 24 or 48 hours. The precise details of the necrosis varied a good deal in different cases; the damage was sometimes central, while in others it had no particular lobular distribution; extensive fatty change might be present or absent; and in one animal considerable portal thrombosis was found. The destruction was in some instances enough to cause death; a pregnant cat had five half-minute "fits," and was killed moribund 18 hours later. Other abdominal organs were not affected, though small hæmorrhages were sometimes found in the lungs and brain. Dr. Theobald draws the obvious conclusion that it is of the greatest importance to prevent the onset or limit the number of eclamptic convulsions.

LONDON'S UNIVERSITY CENTRE

ON Dec. 29th the first excavations were made on the site of the new University of London buildings to the north of the British Museum. The history of this great project has already been outlined in our columns[1] and we printed more recently[2] a reproduction of one aspect of Mr. Charles Holden's model. Four large holes have now been cut at points which mark the corners of the proposed Senate House and administrative block. The object of this survey is to discover the character of the subsoil; the southern part of the site will be excavated at once, and the formal laying of the foundation-stone is planned for the early summer. The new centre will cover 10½ acres and be bounded, roughly, by Russell-square and Montague-street on the east, Malet-street on the west, Byng-place on the north, and the British Museum on the south; its main part includes what was Torrington-square. The main group of buildings is to occupy the centre, and open spaces roughly equal to those which at present exist are to be left along the east and west frontages. The arrangement will greatly reduce traffic noise and vibration and allow generous parking accommodation for cars near each department. The Woburn-square frontage will be occupied by a private garden with a covered walk. As Mr. Holden points out, this type of plan offers great possibilities for a composition of the masses into one great whole which will be impressive even while still incomplete. The group will be dominated by a tower, and the whole centre will be so placed as to appear with quiet insistence from each of the main arteries in the neighbourhood—Tottenham Court-road, Gower-street, Malet-street, and Southampton-row. The composition of the buildings will be seen to its best advantage from Russell-square. Mr. Holden's object has been to express the plan naturally

[1] THE LANCET, 1931, i., 1303. [2] Ibid., 1932, ii., 32.

in a modern design. The orderly disposition of the parts and the strong horizontal character of the whole should present a neighbourly front to the British Museum and the surrounding buildings without the necessity of introducing a columnar treatment. A complete film record of the building is being made.

The scheme will take some years to complete, but should be nearly finished when the University celebrates its centenary at the end of 1936. The Senate House should be ready in 1934. The cost of the site has been met mostly from private benefaction, and important contributions towards the expense of the buildings have been made by the London County Council, Mr. Samuel Courtauld, the Worshipful Company of Goldsmiths, and the Czechoslovakian Government, which has generously promised a sum for the building and equipment of the School of Slavonic Studies.

The new centre will mark a great change for the better in the conditions under which the University does its work. The portion of the Imperial Institute at its disposal is used from cellar to attic and the corridors are filled with makeshift structures, so that the daily work is handicapped by the utmost difficulty and discomfort. For its Great Hall the University has only a huge wooden shed, decorated on festive occasions with yellow and white muslin; and the library, including the Goldsmiths' collection of economic literature and the Durning-Lawrence Library, has long overflowed into passages and rooms continually used for other purposes. If the University is to impress itself upon London and Londoners, it must have a worthy and dignified home. On the new site there will be ample room for the administrative work and for the many bodies which meet daily; the Goldsmiths' munificence will ensure worthy housing of the library; the Institute of Historical Research will be moved from the temporary building in which, in the course of a few years, it has achieved a great reputation, and the Courtauld Institute of Art and the Schools of Oriental and Slavonic Studies will also be housed at the centre. Birkbeck College and the London Day Training College—renamed the Institute of Education—will be transferred, together with the headquarters of the Officers' Training Corps and the Students' Union. The brochure recently issued by the University includes a map showing how well situated the centre will be in relation to the majority of the constituent colleges.

"HOMEOSTASIS"

As man en masse progresses through his pilgrimage he marks his progress by making himself more and more independent of his environment. His cells and tissues have done the same; in birds and mammals they have secured a habitat for themselves of a steady composition and temperature, and have developed a whole series of ingenious and complicated reactions whose effect, and perhaps whose object, is to maintain the remarkable uniformity of the internal environment to which the special mark at 98·4° F. on the clinical thermometer is a characteristic witness. Why it has been worth while to develop cells which will work only under a very limited range of conditions is not altogether clear; an animal which must have its blood-sugar somewhere between about 50 and 150 mg. per 100 c.cm., the reaction of its blood between pH 7·0 and 7·6, and its temperature between 95° and 105° F. would seem to have given hostages to fortune. But so it is, and we can only suppose that the body does its best work in such surroundings. And without thinking too much of the reasons for it, we can with much profit study the "wisdom," as the late Prof. E. H. Starling put it, of the body and its cleverness in making the necessary adjustments to enable its tissues to have the freedom which they gain by escaping from the slavery of their surroundings. The idea dates at least from Claude Bernard, and round it Prof. Cannon has now written an essay[1] which we have no hesitation in commending to all who have any interest in the working of the body—physiologists, pathologists, medical men, and biologists in general. He discusses the regulation—"homeostasis" as he calls it—of the fluids of the body, hunger and thirst, reaction, temperature, oxygen supply, the water, sugar, and proteins of the blood, and especially the rôle of the sympathetic-adrenal mechanism which his own investigations have done so much to elucidate. He deals with the physiology of the body as a whole, not the working of organs, and what he says is obviously of importance as much in the ups and downs of normal life and in disease as in the theory of evolution. We can wish that someone brought up on the other side of the invisible boundary between physiology and pathology would write also of his discipline from the same point of view.

DIPHTHERIA CONTROL IN SOUTH AUSTRALIA

In South Australia, Dr. A. R. Southwood[2] points out, the population is almost equally divided between the metropolitan area and the rural districts, and except when diphtheria is very prevalent, as it was in 1921, the incidence is far higher in town than country. In 1921 the metropolitan cases were but slightly more numerous; after that there was a steep fall in incidence among both sections of the population—especially the rural. This decline was maintained until 1931, when some increase took place, particularly in the metropolitan area. Southwood emphasises the great irregularity in the incidence of diphtheria from year to year, and insists that in any estimate of the effects of preventive measures the statistics over at least 10 or 12 years must be reviewed. It seems that in South Australia active immunisation, on any notable scale at least, was only begun in two of the larger towns of the State in June, 1932; hence, no part of this drop in incidence can be ascribed to it. He admits the value and lack of danger of active immunisation carried out with formol-toxoid (anatoxin), but observes that methods of control applicable to densely populated cities may not be altogether suitable to the sparse populations of the country districts of Australia. The medical officer in face of an outbreak in such a district must be guided by circumstances as to which weapon he is to employ. Amongst these, Southwood urges, none is more potent than early clinical recognition of the disease followed by prompt segregation of the sufferer. Such a step may avert an epidemic. But, epidemic prevalence once established, "a large number of atypical cases occur, and many unsuspected carriers are always at large." During epidemic prevalence, as in the control of endemic infectious disease, the isolation hospital, it is now generally allowed, is of no great value as part of the machinery of prevention. Swift recognition and removal of the *first* cases alone enable these institutions to play their original part with success. Southwood says that the public must be impressed with its duties; a child complaining of sore-throat must be kept apart until diphtheria can be excluded by the physician. Immediate contacts should be swabbed. He quotes with approval the scheme for the control of outbreaks of diphtheria in residential institutions worked out by C. C. Okell, A. J. Eagleton, and R. A. O'Brien [3] which, based upon the Schick test, swabbings and virulence tests, permits of rapid handling of the situation.

---

[1] The Wisdom of the Body. By W. B. Cannon, M.D., Sc.D., LL.D., Professor of Physiology in Harvard Medical School. London: Kegan Paul, Trench, Trubner and Co. 1932. Pp. 312. With 41 figures. 12*s*. 6*d*.

[2] Med. Jour. Australia, Oct. 29th, p. 535.

Warned perhaps by the increased number of cases which occurred in the State in 1931, after a lull of ten years, Southwood fears that storm may follow calm. Although he thinks that in an inter-epidemic period immunisation may not be necessary, yet, when the disease begins to spread rapidly, it would be wise to protect susceptible children by anatoxin. Effort should be concentrated upon children between 1 and 5 years of age for whom, he thinks, a preliminary Schick test is unnecessary "since most of them are susceptible and it is safe to immunise them all." There can be no two opinions, among those competent to judge, as to the value and safety of immunisation, *but whether or not a preliminary Schick test should* to be performed among those of pre-school age is still a subject for debate. Amongst unsalted rural or semi-rural populations the proportion of positive reactors in children of pre-school age is likely to be high, and the omission of a preliminary Schick test may be dictated by this consideration no less than by expediency. In the case of children of pre-school age living in a crowded industrial city, the proportion of immunes may be notably high, and here the omission or otherwise of a preliminary Schick test may have to be decided by expediency alone. The necessity for simplifying the scheme and reducing the number of attendances at the clinic to a minimum may be considered of more importance than the "immunisation" of some children who are already immune.

Expediency also may be the governing factor in determining whether immunisation should be carried out during epidemic prevalence. As Southwood points out, "when people find the illness actively in their midst they are most likely to heed the advice to have their children immunised." The negative corollary of this attitude applies, unfortunately, not only to diphtheria, but to small-pox also.

ON THE TESTING OF HEARING

It is a difficult matter to find a standard by which to measure and record the acuity of hearing and the ratio of the perception of sound by air and bone conduction. A special committee was therefore appointed in January, 1929, by the section of otology of the Royal Society of Medicine to consider various tests of hearing, and this committee has now issued its report.[4] The greater part of its labours has been directed to the use of tuning-forks, as the only efficient method at present known of estimating bone conduction, and these are also recommended for use as the principal method of testing the hearing acuity for air-borne sound. The committee finds that audiometers, as at present manufactured, are scientifically accurate oscillometers, but fail in their application to clinical otology for a variety of reasons. If they are fitted with telephone receivers, these exert different degrees of pressure on the ears, may displace the tragus, allow leakage of sound, or cause error through conduction by the cartilage; on the other hand, if audiometers are used with a loud-speaker in an ordinary room, errors result from reflection of sound-waves. This conclusion does not dispute the use of the audiometer for the detection of deafness in school-children, for which purpose it has been widely adopted, with official sanction [5]; it is a valuable instrument for such preliminary testing, although not sufficiently accurate for consulting-room work.

The committee recommended that the result obtained by testing air and bone conduction by means of tuning-forks should be plotted on a graph; but we hope that the type of audiograph suggested may later be improved and simplified, for it is not easy to understand in its present form. It has been customary to test the degree of deafness by measuring the time that the fork is audible to the normal observer after it has ceased to be heard by the deaf patient, and this is the method recommended; but the committee was faced from the outset by the difficulty that the rate of decay of the vibrations varies enormously with different forks; this rate is estimated by the "half-intensity period" of the fork—that is, by the number of seconds required for the amplitude of vibration to fade by one-half. This period should be between three and ten seconds. In collaboration with the National Physical Laboratory and with the manufacturers, standard forks have been produced, and will shortly be placed on the market; on each fork are engraved its half-intensity period when suspended in air, and when its base is applied to the mastoid, and the relative intensity of the sound transmitted by the prongs and by the base, which is termed the "characteristic" of the fork. When the results of tests with such forks are expressed in half-intensity units, instead of in seconds, the figures so obtained are strictly comparable, though made by different observers and with different forks. This represents a definite scientific advance in the accuracy of testing and recording degrees of deafness, and British otology may well be proud of having given a lead to the world on this difficult subject. The report is amplified by appendices on estimation of the high tone limit, on auditory fatigue, on the use of tuning-forks, on the physics involved, and on audiography; it is carefully written, reflects great credit on the committee, and deserves the attention of all otologists.

PNEUMONIA IN THE STEEL INDUSTRY

The Occupational Mortality Supplement, 1921–23, of the Registrar-General for England and Wales shows that among occupations with an excessive death-rate from pneumonia various groups of workers in the iron and steel industry occupy a conspicuous place. For instance, the comparative mortality figure of puddlers from pneumonia is exceeded by only six out of the 178 occupation groups. The work involved is mainly heavy (and thus a good physical type of recruit is no doubt required) and it involves considerable and probably trying changes of temperature. Some further evidence of this occupational risk was provided in one of the earliest reports of the Industrial Health Research Board,[6] in which Dr. H. M. Vernon included an analysis of the sickness records of about 20,000 steel workers. He found some excess of lost time amongst the men frequently working at high temperatures, but his figures did not permit any fine analysis of cause or causation. A further study has recently been made, for the United States Public Health Service, by Dean K. Brundage and J. J. Bloomfield,[7] and an attempt made to isolate the factors responsible for the high incidence of pneumonia again found. Factors apart from working conditions, such as seasonal variation in the frequency of pneumonia, influenza epidemics, economic status of the workers, their age, nationality, extent of addiction to alcoholic stimulants, and prevalence of the disease in the general community were all considered and found to be of insufficient influence. A calculation of the frequency of pneumonia according to the nature of exposure shows very high rates amongst the men obliged to work out of doors during inclement weather (13·6 per 1000) and for those subjected to heat with wide changes in temperature without significant exposure to any other kind of industrial health hazard (12·6 per 1000), in contrast with a rate of 3·9 cases annually per 1000 exposed to none of the working conditions held to be hazardous. Sudden cooling or chilling of the body the authors believe to be an important predisposing factor, and the importance of its avoidance should be stressed amongst the men, for whom change-houses should be adequately provided. Some of the occupational groups here dealt with are too small to be of real service, but the report represents a careful attempt to reach statistically sound conclusions, though in investigations of industrial hazards it is notoriously difficult to be certain that all extraneous factors have been effectively isolated. This report, however, is but a preliminary, for the full study is to be presented in Public Health Bulletin No. 202, which is still in the press.

ANIMALS AS A RESPONSIBILITY

OUR responsibility towards animals is recognised by all, and the State has legislated widely on their behalf. In his Alexander Pedler lecture[8] for 1932, Sir Frederick Hobday, principal of the Royal Veterinary College, showed the reverse of the shield; we are not, he said, equally alive to the responsibilities towards ourselves which this contact with animals imposes, and we are insufficiently protected against the dangers it creates. Glanders and rabies have been eradicated in this country and are not likely to recur so long as the present preventive legislation is obeyed. He holds also that the timely application of the right methods has done much to stamp out foot-and-mouth disease and anthrax. But the figures he gave for bovine tuberculosis, though familiar, remain remarkable. The average proportion of tuberculous cattle in the dairy herds of Great Britain works out, he believes, at between 30 per cent. and 40 per cent., and in some cases is as much as 60 per cent.; in all there are probably over a million infected cattle. Prof. Hobday quoted figures showing that not only do between 3000 and 4000 children under 5 years die of tuberculosis caught from the cow, but some 45,000 people suffer annually from joint affections the results of bovine tuberculosis with which they have been infected early in life. The consumption of meat also entails danger if, as in England, the animals can be slaughtered at private abattoirs which are often quite unsuitable. The rest of Europe is far ahead of us in this respect, for only in England are animals killed for food which have not been inspected by qualified veterinary surgeons. This country has, as he says, been far behind foreign countries in the governmental support of veterinary research, and Prof. Hobday's lecture lends force to his appeal for donations for the rebuilding and endowment of the Royal Veterinary College.

ZOSTER VIRUS AND BELL'S PALSY

IT is now some 26 years since Ramsay Hunt put forward the view that certain cases of facial paralysis —those associated with a vesicular eruption in the sensory area of the seventh nerve—were due to the zoster virus. And although this syndrome has been recognised and generally accepted, experimental evidence in support of it has been lacking. Elsewhere in this issue, Dr. R. S. Aitken and Dr. R. T. Brain show that cases of the Ramsay Hunt syndrome possess specific zoster antibody in their blood; Hunt's thesis appears to have been correct. But apart from the interest attaching to this demonstration that a proportion of cases of facial paralysis are due to the zoster virus, Aitken and Brain's work has another significance. Quite a number of the filtrable viruses are only capable of attacking a limited number of animal species. Sometimes one species alone is susceptible and this seems to be so with the virus of zoster. Where man is the susceptible species the direct method of experimentation is often precluded, and one has to fall back on indirect means—histological, morphological, and immunological—to provide a solution to our problems. The studies of Netter and his colleagues demonstrating the unity of the clinical group of zoster and the relationship of the zoster and varicella viruses is a good example in point; the work of Aitken and Brain is another.

BROMPTON HOSPITAL REPORTS

WE welcome the appearance of the first number of this new publication, which contains a collection of papers written by members of the honorary staff of the Brompton Hospital for Consumption and Diseases of the Chest and by others working in its various departments. In these days when medical journals, dealing with every ramification of our science, have multiplied to so great an extent that it is difficult for any investigator to keep abreast with all the materials necessary for his work, it is convenient to have a series of papers dealing with a particular branch of medicine brought together into a single volume. The articles here republished indicate that the research department of the hospital is doing useful work. The incidence of tuberculosis upon children has been especially studied, but there emerges, as what may be called a by-product of the investigation by radiological methods, that there are many instances of alterations in the structure of the lungs in children, visible by X rays, which are not due to the tubercle bacillus, and a paper by Dr. F. H. Young deals with the problem of these conditions from a clinical point of view. It would seem that sanocrysin, though far from fulfilling the hopes held out at its introduction, has yet established itself as a useful adjuvant in the treatment of tuberculosis, and a contribution to our knowledge of its mode of action is here made by Dr. E. E. Atkin, who studied its anti-allergic effects in animals inoculated with dead cultures of tubercle bacilli and found a definite inhibition of the formation of tubercles. We hope that future numbers of these reports may be furnished with an alphabetical index to facilitate reference.

[8] Animals as a National Responsibility. The Alexander Pedler lecture of the British Science Guild, delivered under the auspices of the Burton-on-Trent Natural History and Archæological Society, by Prof. F. T. G. Hobday, F.R.C.V.S. Obtainable from the Guild, 6, John-street, Adelphi, London, W.C.2, at 1s.

SPECIAL ARTICLES

NEW WORK ON HORMONES*

BY PROF. W. SCHOELLER
DIRECTOR OF THE HAUPT-LABORATORIUM OF THE SCHERING-KAHLBAUM, A.G.; FORMERLY PROFESSOR OF MEDICAL CHEMISTRY IN THE UNIVERSITY OF FREIBURG

DURING the last few decades research workers have been endeavouring to find out how far the regulation of the female sexual cycle is dependent upon the influence of hormones. It can now be taken as definitely proved that the ripening follicle produces a hormone, or rather a group of closely related chemical compounds, to which we give the name of follicular hormone. The chief function of this hormone is to stimulate the development of the secondary sex organs of the female, such as the uterus, vagina, and mammæ. When the follicle becomes modified to form a corpus luteum the latter generates another hormone which was obtained in concentrated form by Corner[1] in 1929, and the main purpose of which is to stimulate the uterus, which has proliferated under the influence of the follicular hormone, to prepare a decidua suitable for the nidation of an ovum.

These processes occurring in the mature ovary have been shown by Evans[2] to be dependent upon the secretory activity of the anterior lobe of the pituitary body. We are indebted to Aschheim and Zondek[3] for showing that a substance is found in the urine of pregnant warm-blooded animals which is either identical or closely related chemically with the gonadotropic hormone of the pituitary.

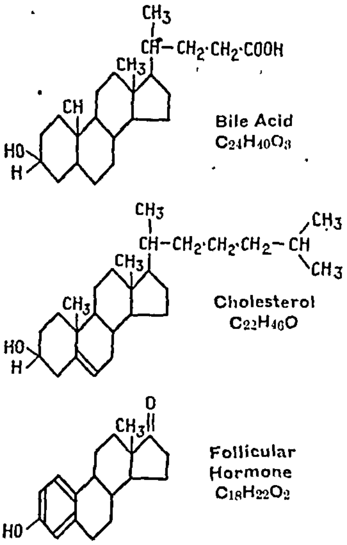
The discovery of the follicular hormone was made possible by the test method elaborated by Allen and Doisy.[4] This method depends upon the cyclical changes occurring in the vaginal secretion of rodents which were observed (1917) by Stockard and Papanicolaou[5] and later (1922) by Long and Evans.[6] By the administration of follicular hormone to castrated female mice and rats it is possible to produce an artificial œstral cycle and during the height of œstrus non-nucleated, horny epithelial cells appear in the vaginal secretions. The occurrence of these is used to standardise the hormone in terms of rat or mouse units. In the normal mature woman only some 100 mouse units of follicular hormone are demonstrable in each litre of urine, but during the later months of pregnancy up to 10,000 units per litre are excreted. The urine of mares in late pregnancy may contain 100,000 or more units per litre.[7]

THE FOLLICULAR HORMONE

The abundant supply of follicular hormone thus available has greatly facilitated its isolation and has made it possible for organic chemists to get busy at clearing up the chemical constitution of this important hormone. First came the classical researches of Butenandt (Göttingen) along with those of Doisy (St. Louis) and Marrian (London). In 1929 *Doisy and Butenandt, working independently,* were able to prepare the hormone in pure crystalline form. According to Butenandt,[8] the hormone has the formula $C_{18}H_{22}O_2$ and is a partially hydrated phenanthren derivative, one of the oxyketones. The phenanthren ring appears to be joined to a pentagonal ring system. Its constitution thus seems to be very similar to that recently demonstrated for the sterols and biliary acids.

The follicular hormone occurs in several isomeric forms, which differ in their activity. α-follicular hormone has, according to Butenandt,[8] an activity of 10-million mouse units per gramme, while the β form contains only 1½ million units. A third highly active isomer was recently described by *Schwenk and Hildebrandt.*[9] *Marrian*[10] was able to isolate a compound closely related to the hormone but containing more oxygen, the so-called follicular hormone hydroxide with the formula $C_{18}H_{24}O_3$, which Butenandt[8] was able to reconvert into the α and β forms of the hormone by splitting off water. In the hydroxide the three oxygen atoms are present as hydroxyl groups, one of which has the characteristics of a phenol. The substance has an activity of only 75,000 mouse units per gramme. Recently Girard and his co-workers[11] have reported upon two further isomers closely related to the follicular hormone, equilin and hippulin, which they extracted from mare's urine. Further, Laqueur[12] and Marrian[13] were also able to isolate further products, the constitution of which has not yet been determined.

FIG. 1



Graphic formulas of the follicular hormone and some chemical allies.

We do not know whether all these variants are necessary for the female sexual cycle, each carrying out part of the function, or if they are derivatives of the hormone proper metabolised perhaps for the purposes of excretion. This chemical complexity puts obstacles in the way of gynæcologists who have sought to determine the functional capacity of the ovary by estimating the amount of hormone in mouse units excreted in the urine. For example, if the α hormone is converted into hydroxide for the purpose of excretion this would produce a drop in the number of mouse units from 8–10 millions to 75,000 or so, and the investigator would thus be led to underestimate the output of the ovary.

The occurrence of the follicular hormone is not restricted to the animal kingdom. From the work of Loewe,[14] Dohrn,[15] and others we know that it also occurs in plants as, e.g., in germinating grain. This observation is particularly valuable since it shows a new link between the animal and vegetable kingdoms. Relevant hereto are Aschheim's[16] brilliant findings; in association with Hohlweg, he was able to prepare an oil containing the hormone from peat, coal, and petroleum. It is astounding that follicular hormone originating from plant or animal material should have remained undecomposed during the æons required for the formation of mineral coal or petroleum. According to estimates based upon amount and character of radio-active decomposition products, the age of Westphalian coal is estimated at 120 million years, and from it these workers were able to isolate a crude hormone oil containing some 3000 mouse units. When one considers how much coal is burnt yearly to obtain heat and energy it will be seen that the quantity of follicular hormone which is destroyed at the same time must amount to thousands of kilos.

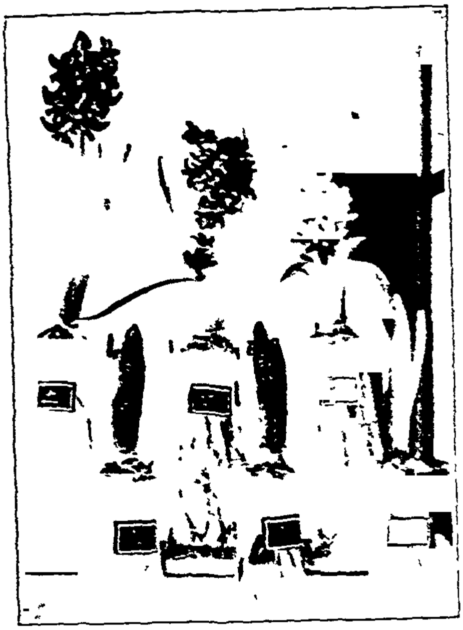
FIG. 2



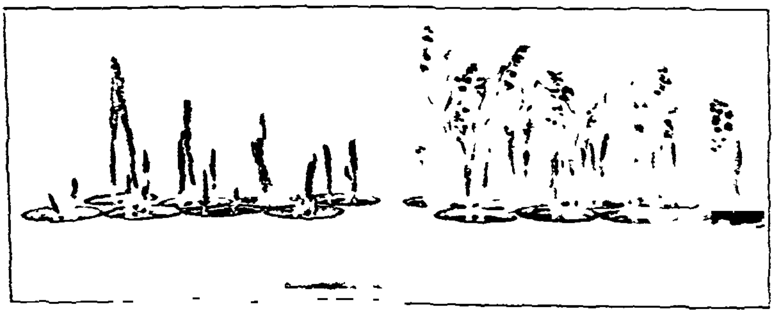
Above, three hyacinths growing in water to which was added over a period of six weeks 200 mouse units of progynon (œstrin). Below, three controls.

PLANT HORMONES

The action of the follicular hormone is not restricted to animals. Experiments of Schoeller and Goebel[17] have shown that the supply of small quantities of this hormone may accelerate the flowering of certain plants—e.g., hyacinths, arum lilies, and lilies of the valley. This work contained the first proof that the principle of hormone action established for animals evidently holds good also for plants. It opens up the questions vital to plant physiology; where are such substances produced and what other functions of plants are under hormonal control?

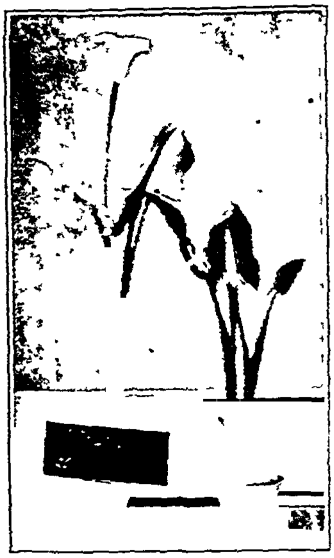
From this point of view the work of Went and Kögl (Utrecht) is worthy of close attention. The classical work of Went[18] on the decapitated Avena shoot has shown that phototropism (turning of plants towards the light) and *geotropism* (reaction of plants to gravity) are due to a chemical substance. This substance has the power of expanding plant cells and as it accumulates on the shady side in the one case or in the direction of gravity in the other it distends the cells and causes rotation of the plant. Recently Kögl[19] was successful in isolating this hormone, which he called auxin, in pure crystalline form. Its formula is $C_{18}H_{32}O_5$ and its chemical structure that of a trioxycarbonic acid. It is a remarkable fact that auxin also occurs in warm-blooded animals, but in them nothing is known of its action, other than that it is excreted in the urine. Through this work some insight is gained into two further secrets of plant life, and it remains to be seen whether leaf and root formation are also due to the stimulus of a hormone.

FIG. 3



On the right, lilies of the valley, which after supply of 300 mouse units of progynon (œstrin) weekly are vigorously flowering, compared with controls on the left.

FIG. 4



On the left, arum lily flowering under the influence of crystallized progynon (œstrin), and again a second time after the first flower withered, when further hormone was supplied. On the right a control.

THE CORPUS LUTEUM HORMONE

As was mentioned at the outset the presence of a second hormone, which is found in the corpus luteum, is essential to the female cycle. The fact that the corpus luteum exercises an endocrine function was shown by the work of Fränkel,[20] Buin and Ancel,[21] and Hammond and Marshall.[22] It was however Corner and Allen[1] who first obtained active extracts of the hormone and were able to maintain pregnancy after castration by their use. In Germany, Clauberg,[23] and in Austria, Knaus[24] have studied the effect of this hormone, while Fels and Slotta[25] claim to have isolated it in crystalline form.

According to Steinach and Kun,[26] the corpus luteum also produces the male hormone so that during the fourth week of the intermenstrual period, and in the early months of pregnancy, a woman is apparently bi-sexual. Corresponding with this observation, Womack and Koch[27] found male hormone in the urine of both normal and pregnant women and conversely, according to Dingemanse and Laqueur,[28] follicular hormone can be isolated from male urine.

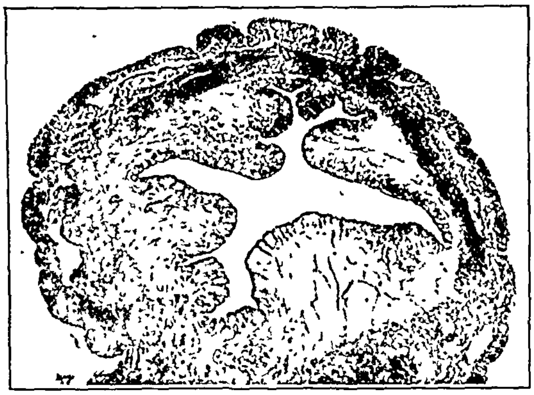
That the sexual cycle of women demands a reasonable supply of both these hormones, follicular and corpus luteum, was recently demonstrated by Kaufmann.[29] Injections of 320,000 mouse units of *a follicular hormone derivative (progynonester) in the* course of 18 days, followed by injections of 90 rat units of corpus luteum hormone in a woman castrated some years before, caused bleeding of four days' duration. In this menstrual blood he was able to demonstrate under the microscope elements of decidua; the atrophied uterus had proliferated so far as to develop under the influence of the corpus *luteum hormone a real secretory phase.*

THE MALE HORMONE

The story of the male sex hormone begins with the experiments made by Berthold [30] (Gottingen) in 1849 on the growth of the comb in capons into which he implanted testicles from sexually mature cocks. Although he drew the correct conclusion that the blood of the capons must have become altered in such a way as to allow their combs to grow again, neither he nor his contemporaries carried this very valuable observation any further. The famous experiments of Brown-Séquard [31] upon himself, which he presented *to the Paris Academy 40* years later, also remained inconclusive. We owe it to the untiring efforts of the Chicago workers, Koch, Moore, and Gallagher [32] that crude extracts of bovine testicle were so far purified as to produce an effect on the combs of capons. Casimir Funk [33] is to be credited with the proof that the male hormone is excreted in the male urine, and can be prepared from it. Laqueur [34], and his school have made a valuable contribution to the standardisation of the hormone by devising the method whereby the shadow of the comb is reproduced on photographic paper and measured planimetrically.

A second test devised (1930) by Loewe and Voss [35] is based on the work of Steinach and the American school on the effect of male sex hormone on the secondary sex characteristics of castrated male rodents. The hormone is capable of producing externally visible regeneration of the atrophied seminal vesicles of castrates, corresponding in degree to the amount of hormone administered. Loewe observes the histological changes which precede this process. In the same way the hormone causes regeneration of the prostate, penis, and vas deferens of castrates

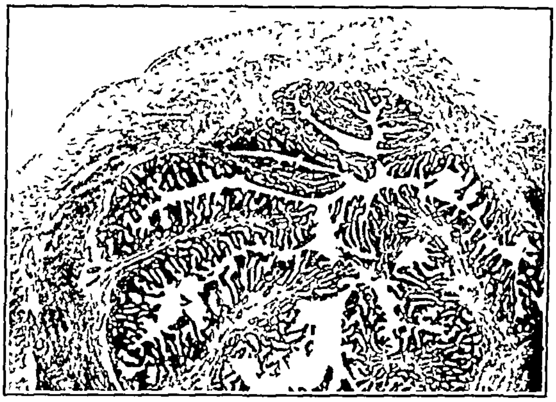
FIG. 5



Proliferation of the uterus of a castrated rabbit after treatment with 105 mouse units of progynon (œstrin).

Again it was Butenandt [36] who was the first (1931) to prepare the male sex hormone in pure crystalline form from a hormone oil prepared according to a process devised by Schoeller and Gehrke [37] and supplied to him by Schering-Kahlbaum, A.G. The hormone has the formula $C_{16}H_{26}O_2$. It is also an oxyketone, but its hydroxyl group has the character of a secondary alcohol and not that of a phenol. It must be considered as a saturated system; whether it also belongs to the class of phenanthren derivatives, and is therefore closely related chemically to the female sex hormone, remains to be seen.

FIG. 6



Transformation of mucosa into decidua under the influence of corpus luteum hormone (Schering). Observation of Clauberg.

Further, it is not yet known whether the male sex gland produces one hormone only, or whether *its several effects are produced by different, even* though closely related, components.

ANTERIOR PITUITARY HORMONE AND THE SEXUAL CENTRE

Controlling both male and female genital glands there is the gonadotropic hormone of the anterior lobe of the pituitary, the action of which has been described in the works of Evans, Engle, Smith, Steinach,[38] Aschheim and Zondek.[39] Whether it is identical with prolan isolated by Aschheim and Zondek, obtained from pregnant urine, has not yet been definitely established. These workers have been led to believe that two separate components, prolan A and prolan B, are essential for the control of the ovarian cycle: A for the production of mature follicles, B for luteinisation. Neither the preparation of these two components in pure form nor their separation has yet been accomplished. The abundant excretion of prolan in the early days of pregnancy is the basis of the well-known Aschheim-Zondek reaction.

The study of the reaction of the gonads on the hypophysis has produced interesting results. Fichera [40] and other authors noted under the microscope, in the anterior lobe of the pituitary after castration, the appearance of large clear cells, the nuclei of which contain little chromatin, the so-called castration cells. Evans and Simpson [41] were able by means of implantation experiments to show an increased action on the gonads parallel to this histological change. Finally, Hohlweg and Dohrn [42] demonstrated *that this reaction of castration on the* hypophysis could be completely annulled by administration of sex hormone, a method which enabled them to estimate the production of hormone by the gonads of young warm-blooded animals (rats).

The reaction of the sex hormone on the hypophysis is, according to Hohlweg and Junkmann,[43] not a direct one, since in rats, in which a second hypophysis had been implanted in the kidney, castration produced the characteristic changes only in the hypophysis which was normally situated. The appearance of these changes must therefore depend upon nervous influences which can only reach the animal's own hypophysis. This fact leads Hohlweg and Junkmann to assume the existence of a sexual centre, the site of which, from observations made by Teel and Cushing[44] on deficiency symptoms due to tumours, is probably in the floor of the third ventricle. If this is so the self-regulating control of the gonads may be expressed in some such scheme as Fig. 7.

This scheme explains also the valuable observation of Philipp[45] that the anterior pituitary lobe of pregnant women contains extraordinarily little gonadotropic hormone. Philipp assumes that during pregnancy prolan is elaborated in the chorionic portion of the placenta. Whether the gonadotropic hormone of the anterior pituitary is chemically identical with the prolan produced in the chorion is, as Freud[46] (Amsterdam) has very properly emphasised, not yet known, in spite of the great similarity in their action.

In a similar way, for the purpose of future experiments, it may be taken as a working hypothesis that the luteinising principle, necessary for the control of the female sex cycle, is not produced in the hypophysis but depends upon hormonal influence on the part of the ovum. Thus, if the unfertilised ovum dies in the normal way, the corpus luteum also perishes within a short time, whereas if, on the other hand, the ovum is fertilised and nidation takes place, the corpus luteum persists until the embryo has become independent. Again, according to this hypothesis, metropathies would be explained as the result of a lack of functionally active mature ova.

FIG. 8

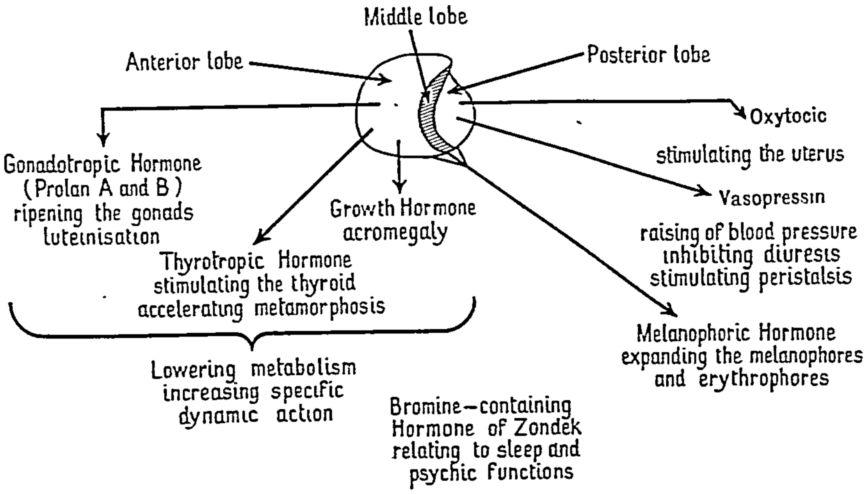


Diagram of collective function of pituitary.

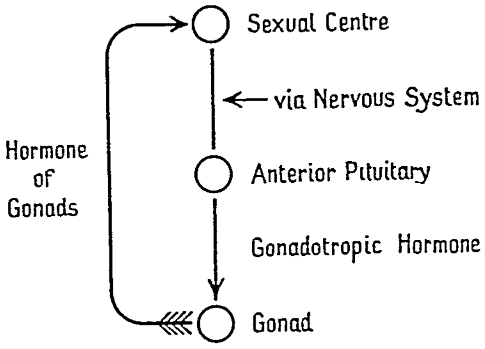
THE THYROTROPIC HORMONE

While the gonadotropic hormone of the anterior pituitary has the function of stimulating the activity of the gonads, its thyrotropic hormone exercises a similar effect on the thyroid. The work of Loeb,[47] Aron,[48] Jansen and Loeser[49] has shown that this hormone can eliminate colloid from the thyroid and stimulate the follicular epithelium. According to Junkmann and Schoeller[50] the hormone may be conveniently standardised by means of the thyroid of the young guinea-pig. Apparently the hormone can also produce the transformation of the axolotl. Its effect presumably is to raise the level of thyroxin in the blood. This also explains the heightened basal metabolism and the reduction of the glycogen content in the liver. Schittenhelm,[51] experimenting with large doses on voluntary patients, was able to produce early symptoms of Basedow's disease which then rapidly subsided.

FIG. 7



Scheme of self-regulating control.

With the help of its gonadotropic hormone the anterior lobe of the pituitary stimulates the gonads to produce the specific sex hormone, the function of which is to develop and maintain the secondary sex characteristics. The sex hormones circulating in the blood act on the sexual centre which, according to whether the level of sex hormone in the blood is above or below normal, inhibits or stimulates the further production of the gonadotropic factor.

From the chemical standpoint the thyrotropic hormone belongs, together with the gonadotropic hormone and insulin, to the class of hormone which is closely related to the proteins. They undergo digestion and are therefore inactive when given by the mouth; further they are more or less sensitive to heat and to hydrolysing agents. They are for the most part soluble in water, slightly soluble or insoluble in organic solvents.

Our present knowledge of the collective function of the hypophysis may be expressed in a diagram (Fig. 8).

The purpose of this summary of recent researches on hormones is to enable those who are not specialists in this field to study the original publication in this or that branch of the subject.

OUT-PATIENT DEPARTMENTS

THEIR USE AND ABUSE

In January last the Prince of Wales, as president of King Edward's Hospital Fund, appointed a special committee "to inquire into and report upon the methods in use in the London voluntary hospitals regarding the attendance of patients in the out-patient and casualty departments, and the effect of those methods upon the suitability of the patients treated and on the length of time during which patients wait before or after treatment." This committee has now issued a report,[1] which includes a historical survey of the out-patient department, a review of the present position, and a general description of procedure, as well as a full discussion of the committee's terms of reference.

The report points out, in the first place, that the question of suitability falls into two parts—medical and financial—and that the out-patient department proper must be considered separately from the casualty department. Secondly, it stresses the gradual change that has come over the out-patient departments of voluntary hospitals, which were originally places for the simple treatment of the sick-poor, but are now available to members of contributory schemes and to patients who pay a moderate fee, and which provide every year an increasing amount of complex service and treatment which is not available elsewhere at a reasonable charge.

The committee has no doubt that the hospitals maintain their popularity, and all the evidence confirmed the statement that they had the confidence of the working-class population. The annual attendances at the twelve teaching hospitals have increased from two and a half million in 1911 to nearly four million in 1931. There was, however, a drop in the number of medical patients after the passing of the National Health Insurance Act, and this has not been made up, although the figure has been rising since 1917. The surgical figures were not affected by the Act. The discrepancy between patients and attendances since 1911 and the increase in medical patients since 1917 probably reflect the increasing number of complex diagnostic measures which require hospital attendance, and of special treatments that need repeated visits, as well as a rise in the average seriousness of the hospital medical case. Very few complaints have been received from patients, and these were mostly concerned with waiting and overcrowding, and not with any inefficiency or inadequacy of service. The committee realises, however, that there is no channel for complaints and thinks it important that there should be one.

TIME OF WAITING

There seems to be no doubt, despite the vagueness of some of the evidence, that patients do have to waste a good deal of time in out-patient departments, though not in casualty departments or special departments, except those for eye and ear.

Four chief theories of the cause of delay have been put forward to the committee. One regards waiting as inevitable and only to be obviated by quite impracticable increases in staff and accommodation; another puts it down to overcrowding and thinks that it could be remedied by improvements in accommodation; a third ascribes it to remediable defects in procedure; and a fourth to unsatisfactory selection of patients, many being sent to the consultant when they could properly be treated elsewhere. There are hospitals which still maintain that their doors must always be open to all-comers, and there are others who will admit only patients bearing a letter from a medical man. On the whole, hospitals are tending more and more towards the latter extreme, and emphasising the consultative nature of the service they offer. The British Medical Association has suggested that doctors' letters should be compulsory except in cases of emergency. The committee is not able to accept this view, although it supports the movement towards the more consultative use of the out-patient department. It thinks that patients who cannot pay a consultant fee and who

want a second opinion should be able to get one at a hospital without having to obtain a letter from a general practitioner; they may be shy of asking him, or they may not be in touch with a doctor; and the doctor is by no means necessarily the best person to decide whether or not a hospital opinion is desirable.

THE "MINOR AILMENT" CASE

An undoubted cause of overcrowding and consequent waiting is, in the opinion of the committee, the treatment of large numbers of "minor" cases, and the question of alternative provision for these is therefore a very pertinent one. It is bound up to some extent with the problem of financial suitability. Some hospitals feel that a patient who is so poor that he cannot obtain the necessaries of life or pay the smallest fee is not likely to benefit from treatment, and had better be dealt with by the public assistance authority, which can supply both medical treatment and any form of relief required to make it effective. Other hospitals hold to the older idea that they were founded for the treatment of the sick-poor and must turn no one away. A far larger class comes within the "income range" established by the hospitals and could, in the opinion of the British Medical Association, afford to pay general practitioners for treatment for these minor ailments or could obtain what they need by means of an insurance or provident dispensary scheme. There is yet a third class with incomes above the range of public assistance who yet find a general practitioner's fees a severe charge on their incomes. Nevertheless, when all exceptions have been excluded, there remains, in the opinion of the committee, a very considerable number of patients attending hospitals for minor complaints which could properly be treated elsewhere. The report discusses at some length the alternative provision available for these people.

In so far as they are not treated by the consultants personally, they must be referred either to general practitioners or to the junior staff of the hospital. Some authorities argue that the junior staff are more up to date and efficient than the general practitioners; others that they lack the breadth of view and experience of the man outside. While not feeling called upon to express an opinion on the merits of the practitioner, the committee points out that treatment of minor ailments by the junior staff will not greatly assist the problem under consideration: overcrowding of the hospital. The report therefore urges greater coöperation between hospitals and practitioners—for the benefit of both.

Besides private practitioners, there are provident dispensaries, public medical services, charitable dispensaries, voluntary and public clinics, public assistance provision, and nursing services. All of these could play their part in relieving hospital congestion, and the committee stresses the importance of coöperation with them all. It further recommends that hospitals should do all they can to let doctors know the hours of the various consultants, so that patients are not sent up with personal letters on the wrong days, and to send reports on cases, while doctors should supply adequate case-notes when sending their patients to hospital. A vicious circle is very apt to develop, and goodwill and a realisation of the value of each to the other is necessary if practitioners and hospitals are to make the best possible use of each other for the best service of their patients. Against the additional work required for coöperation might be set the reduction in numbers. The more competent and experienced the doctor who does the sifting, the less the likelihood of mistake or dissatisfaction. Sifting takes time, but the time is probably saved in other departments. The problem of minor cases cannot be considered without reference to the needs of the medical student, but the committee is of opinion that, although the minor case is necessary for education, great reduction in the present numbers could be effected without harming the teaching work.

DELAY DUE TO PROCEDURE AND LACK OF ACCOMMODATION

The report discusses carefully the various procedures by which out-patients are received, registered, and interviewed, but is unable, amidst the diversity, to pronounce a judgment on the best method. It desires further records of time-counts showing how long each way takes, and advises all hospitals to consider whether changes in procedure might not accelerate the service. Time may be saved by arranging special sessions for special classes of patient—e.g., discharged in-patients, young people between 14 and 16, and so on. The appointments system has been warmly defended by some hospitals, whether the appointment be given to individuals or to groups, and the committee feels that this possibility demands attention. Some hospitals limit the number of patients that may be seen at a session, and others offer a number of improvements in general organisation that the committee recommends to the consideration of those who have not adopted them already. Even if the time of waiting is not reduced thereby, the grumbling at it may be effectually stopped by seeing that the waiting-hall is warm and comfortable and that refreshments are available.

Waiting time is certainly reduced by the provision of adequate dressing rooms and examination rooms, and by the existence of suitable special accommodation for special departments. Time is saved if patients do not have to traverse long corridors from one room to another.

THE COMMITTEE'S CONCLUSIONS

In summary, therefore, the chief conclusion of the committee is that the out-patient problem can be materially reduced by sifting out a large proportion (but not all) of the minor cases and arranging for their treatment elsewhere than in the consultant's room. The hospital should be prepared to use to the utmost all coördinated services to which patients can be referred, and should particularly endeavour to satisfy the requirements of the general practitioner who, in his turn, should do all in his power to use and accelerate the service the hospital can render him. The committee thinks the present movement towards a more consultative service is a movement in the right direction, but does not recommend carrying it to the extreme of excluding patients who desire a second opinion and cannot afford it privately. It views with favour the proposal to supply both practitioners and consultants with standard forms to send with the patients. Every hospital, it considers, should study the procedure in use at other hospitals and consider whether there is not room for improvement in its own routine. The King's Fund is advised to see how it can help the hospitals to carry out the committee's recommendations.

NORTHAMPTON GENERAL HOSPITAL.—The report for 1932 shows 4629 in-patients, an increase of 422 on last year; of these 1772 were accidents and emergencies. Average stay, 18 days, cost £7 14*s.* 5*d.*, and cost per bed per day 8*s.* 10*d.*—small reductions under each head. Out-patients exceeded 19,000, an increase of more than 800, who cost 7*s.* 2*d.* each. Ordinary income £43,143, expenditure £44,278.

THE VALUE OF MASSIVE RADIATION

FINAL REPORT OF THE CONFERENCE ON RADIUM

THIS Conference owed its origin to doubts publicly expressed as to the soundness of the decision of the Radium Commission to withdraw the 4-gramme bomb, then in use for massive radiation at the Westminster Hospital, and subdivide it into four units of 1 gramme each. It consisted of the following members :—

Lord Dawson of Penn, President of the Royal College of Physicians of London, in the chair.

Lord Moynihan—now succeeded by Sir Holburt Waring—President of the Royal College of Surgeons of England.

Mr. Wilfred Trotter, representing the Medical Research Council.

Sir Frederick Menzies, Chief Medical Officer, L.C.C.

Dr. Watts Eden, President of the Royal Society of Medicine.

Mr. H. S. Souttar, representing the B.M.A.

Prof. Arthur Hall, Mr. Ernest Miles, and Prof. Woodburn Morison, representing the Radium Commission.

INTERIM REPORT

In an interim report, dated March 4th, 1932,[1] the Conference decided unanimously :—

(1) That the Radium Commission arrived at a sound conclusion in discontinuing the use of the 4-gramme bomb at the present juncture, though this decision is without prejudice to the question of the therapeutic value of 4 gramme or even larger aggregations of radium.

(2) That in the opinion of this Conference a fully equipped radium institute is needed in London, where the more difficult and speculative problems connected with radium and ray therapy can be studied by the combined efforts of a trained staff.

The Conference appointed a technical committee as follows :—

Chairman.—Mr. H. S. Souttar.

Physics.—Lord Rayleigh, F.R.S., Prof. J. C. M'Lennan, F.R.S.

Radiotherapy and Medicine.—Dr. Roy Ward, Radium Institute; Dr. G. F. Stebbing, Lambeth Hospital, L.C.C.; Dr. B. W. Windeyer, Middlesex Hospital.

Surgery.—Mr. Cecil Rowntree, Cancer Hospital; Mr. Geoffrey Keynes, St. Bartholomew's Hospital.

Gynæcology.—Mr. Louis Rivett, Middlesex Hospital; Dr. Elizabeth Hurdon, Marie Curie Hospital.

Experimental Radiation.—Dr. W. Cramer, Imperial Cancer Research Fund Laboratory.

Representatives of the Conference.—Lord Dawson and Lord Moynihan.

FINAL REPORT

This committee reported finally on Dec. 19th, 1932. After considering their findings, which are set out below, the Conference has issued a short statement which runs :—

"It is clear that there is a field of usefulness for radiation from massive units of radium, given an adequate equipment and men and means. We adopt the view of our technical committee that it is desirable that a radium unit containing not less than 5 grammes of radium element should be established.

"An institute specially constructed for the purposes of such radiotherapy and within easy reach of the future Post-graduate School and Hospital is an ideal to be aimed at, but for the moment it may be impracticable upon financial grounds. It would, however, be feasible to organise existing institutions for the time being, provided they were near enough to each other for efficient coöperation. The amount of radium required for a large unit might mean that the allotment of radium by the Radium Commission would need to be further concentrated.

"Both X ray and radium therapy are at present advancing so rapidly that it is impossible to decide the position which each will occupy in the future. The whole field is one for the fullest investigation, and it is one in which results of the first importance have already been obtained.

"In drawing up this report," which is signed by Lord Dawson, "the Conference has purposely refrained from considering the relative places occupied by surgery and radiotherapy in the treatment of malignant disease."

Two Questions Submitted to the Technical Committee

The technical committee were asked for a reply to these questions :—

1. What is the scientific case for mass radiation by radium, and what are the advantages and dangers attaching to the use of such radiation ?
2. What are the advantages and risks of massive surface radiation by radium compared with those of radium needles and radon seeds ?

Their report, which is a reply to the questions, is as follows :—

Selective action of radiation upon malignant cells.—The use of radium in the treatment of malignant tumours depends upon the empirical observation that in a large number of instances the cells of malignant tumours are destroyed by an amount of radiation insufficient to destroy the normal tissue. This proposition is generally true over a very large range of wave-lengths, and certainly holds over a range which extends from X rays with a wave-length of 1 A.U. to hard gamma rays with a wave-length of 0·04 A.U. or less. In spite of an immense amount of research devoted to this particular point, it is still uncertain whether there is any specific difference between the longer and shorter waves in their effect upon the cells, although there is a general impression that radiation of short wave-lengths has a higher degree of selective action upon the cells of malignant tumours in virtue of their rapid growth.

Penetrating power of short waves.—What is, however, quite certain is the physical fact that radiation of short wave-length has a higher penetrating power, and is therefore capable of conveying energy into the deeper tissues, whilst radiation of longer wave-length is absorbed in the more superficial tissues and there expends a large part of its energy. It is for this reason that X ray apparatus is being made to generate X rays of shorter and shorter wave-length, but no apparatus has yet been devised to generate waves as short as the gamma rays of radium. These short wave generators are still on trial, and it is of importance that we should be able to compare the results obtained from them with those obtainable from mass radiation by radium.

PROBLEM OF THE UNIFORM FIELD

The margin between general destruction of the tissues and selective destruction of the malignant cells which are invading them is very small, and it is therefore an essential factor in treatment that every element of tissue throughout the region treated should receive exactly the same amount of radiation, for if at any point there is a defect some malignant cells will survive; whilst if at any point there is an excess the supporting tissues will be destroyed. In the treatment of malignant tumours by radiotherapy, whether by means of X rays or of radium, there is indeed a general agreement upon the importance of obtaining a uniform field of radiation throughout the region under treatment. Whatever method has been adopted its clinical success has always been proportional to the accuracy with which this physical problem has been solved, and there are strong grounds for believing that upon its more complete solution may depend the whole future of radium therapy in the treatment of cancer.

---

[1] See THE LANCET, 1932, i., 1110.

So far therefore as our present knowledge is concerned, the solution of the exceedingly complicated clinical problem of the treatment of malignant tumours by radiation would appear to depend primarily upon the solution of the physical problem of obtaining a uniform field of radiation—that is to say, a field throughout which the scalar value of the energy absorbed is constant both in the cross section and in the depth of the field.

The advantage of gamma rays.—For this purpose gamma rays present a very definite advantage over X rays, since owing to their shorter wave-length they have a proportionately greater penetration. Although in both instances the intensity of the field diminishes with the distance from the source, it is far less affected in the case of gamma rays by the absorption of the tissues, and it is therefore easier to maintain a uniform field as the depth below the surface increases.

It is true that the great volume of power available in the modern X ray tube allows of a greater working distance, so that the proportion of energy delivered in the depth of the body by X rays may be equal to or even greater than that obtained from radium. But the use of such a volume of energy presents a disadvantage, since there is general agreement that X rays produce more constitutional disturbance than do gamma rays of equal adequacy, possibly owing to the more complete absorption which X rays undergo in the tissues.

The relative value of the two methods can only be discovered by further experience.

MODES OF APPLYING RADIUM

Massive radium units at a distance.—The use of massive units of radium outside the body furnishes a powerful means of subjecting a region of considerable volume to a uniform radiation by gamma rays, and if a sufficiently large quantity of radium were available this would prove the most perfect physical solution of the problem. It is not, of course, sufficient to use a single beam, since the unavoidable fall in intensity as the distance from the surface increases necessitates a dosage which exposes the proximal tissues, and especially the skin, to an excessive radiation. This, however, may be overcome by the use of multiple ports of entry, and by exact calculation an almost perfectly uniform field can be obtained throughout any volume of tissue where it is required.

Other methods.—The difficulty of obtaining sufficient radium for use by this direct method has compelled surgeons to devise other methods, by which radium, being brought into closer contact with the tissues, is used to greater economic advantage. The application of radium plaques, the insertion of needles, and the insertion of seeds all come under this heading, and there is no doubt at all that when properly applied in suitable regions they may combine economy with efficiency. They present a further advantage that, owing to the smaller amount of radium used, the effects are strictly localised, and neither the patient nor the attendants are exposed to the possible dangers associated with large quantities of radium.

Defects and limitations of interstitial methods.—Although these methods have in many instances given brilliant results, and are probably of permanent value, they present the disadvantage that they do not produce the ideal uniform field of radiation, and in spite of their success it is still an open question whether massive radiation may not produce even better results when applied to the same situations. This view is certainly supported by the work of Berven on cancer of the buccal cavity, where the results obtained are far superior to those which have hitherto been accomplished either by surface or interstitial methods. The question is one of the greatest importance, but it can only be settled by future work.

The use of needles and of seeds is further limited by the fact that it necessitates surgical access to the region of the tumour, and not merely to the tumour itself but to the whole of the neighbouring lymphatic area through which it may disseminate. This is often undesirable and frequently impossible, and indeed there is only a limited number of situations in which it is possible to treat effectively by these means the whole region under suspicion.

Regions still to be explored.—In spite of the variety of methods now available it is still only in special instances that radiotherapy has been applied to cancer with success, and there remain whole regions where this has not yet been achieved or even seriously attempted; as examples we may cite deep-seated tumours in the thorax and abdomen. It is here that massive radiation with its penetrating rays appears, at first sight, to offer the solution of the problem, but difficulties arise which are not merely physical but are inherent in the disease.

Such tumours are inaccessible to early diagnosis, and in the great majority of cases are far too advanced when diagnosed for treatment of any kind to be successful. They arise often in tissues which are themselves very radiosensitive such, for example, as the stomach, the intestine, and the rectum, and the annihilation of the tumour may involve the destruction of the organ from which it has sprung. Moreover, the exact extent of lymphatic involvement cannot be determined, so that it is difficult to ensure the complete irradiation of all malignant cells.

In spite of these difficulties there are definite grounds for hoping that by some combination of irradiation and surgery even cancer of the alimentary tract may ultimately be brought under control. In this achievement it is the definite opinion of such cautious observers as Forssell and Regaud that radiation from a distance, either by massive radium units or by X rays at a potential not yet obtained, will play an essential part.

THE DANGERS OF RADIUM

Although there is still very little known about the precise action of gamma rays upon the tissue cells, practical experience is so far advanced that any of the methods which we have mentioned may be employed by experts without danger either to the patients or to themselves. In the hands of the inexperienced the use of radium in any form is dangerous, and an attempt to assess the degree of danger would be more curious than useful.

The insertion of seeds or needles or the application of local plaques in expert hands leads to the disappearance of a tumour with only a moderate local reaction, and, except in the case of a large tumour, with very little constitutional disturbance. A faulty estimation of the dosage or an uneven distribution may lead to gross destruction of the tissues, extensive ulceration of a most painful and intractable type, and even to the death of the patient, whilst there can be no guarantee that the tumour itself has been destroyed. It is true that with a larger mass of radium destruction might be extended to an even wider sphere, but that is the only difference.

All the evidence before us goes to show that the use of massive units of even the largest dimensions can be so completely controlled that the safety of the patient is assured. The occurrence in some instances of severe constitutional disturbance has always been due to some error in technique, and has been avoided on further experience. We are satisfied that there is no foundation for the idea that the use of a massive unit is necessarily associated with any special danger to the patient.

CONCLUSION

The evidence has convinced us that the treatment of cancer by radiation from a massive radium unit (tele-radium) is a method the value of which has already been proved, although so far only in a limited field. How far these limits can be extended is a question which can be solved only by coördinated clinical, experimental, and physical research in which this country ought to take its share. The larger the unit available the more rapidly will its possibilities be discovered, and the wider will be the field which can be explored.

After a full consideration of all the evidence available we are convinced that a large radium unit should be erected in this country, under conditions where such coördinated effort is possible, containing not less than 5 grammes of radium element.

Material on which Report is Based

The technical committee held eight meetings, the first at the Royal College of Physicians on June 16th, 1932. Visits of inspection were made, including one to the Westminster Hospital annexe. The report is based upon personal experience in the various branches of radiotherapy to which members of the committee individually devoted special attention, and upon personal observations following visits to radium centres in London, Manchester, Birmingham, Paris, Brussels, Stockholm, and New York. The committee heard evidence from Prof. Sydney Russ, Mr. E. Rock Carling, and Mr. Stanford Cade, and saw a confidential report from Mr. Comyns Berkeley, who had visited most of the European radium centres on behalf of the League of Nations. To obtain the latest information about the progress of treatment by massive units, Prof. M'Lennan and Mr. Souttar paid visits to the radium institutes of Paris and Stockholm.

VISIT TO PARIS

In an interview with Prof. Regaud at the Institut Curie he stated that his experience of the use of 4 grammes of radium for distance therapy began in 1924, and had extended continuously over eight years, during which only minor alterations had been made in the construction and mounting of the apparatus.

The apparatus consists in a square lead box with walls 6 cm. in thickness, and with an internal area of 150 sq. cm. The radium is contained in 80 platinum tubes with walls 1 mm. in thickness, and is arranged in four groups of 20 tubes each on an internal frame, so that they are situated at the corners of the lead box. The opening of the box is closed up by a block of wax of such dimensions that the plane of the radium is at a distance of 10 cm. from the skin of the patient. As a general rule the treatment extends over 70 hours, and is divided into doses of from two to four hours according to the tolerance of the patient.

Prof. Regaud had never seen any injury to the patient, either local or general, nor any evidence that the treatment had been injurious. Sensitive patients often experienced sickness after the treatment, but this soon passed off and did not recur if a diminished dose was given on the next occasion.

Carcinoma of the stomach.—Twenty-five cases had been treated after surgical exploration, which had proved that the case was in fact carcinoma and inoperable. In the first group of cases the dose was inadequate (600–900 mc.d.), and no effect of any kind was observed. In later cases the dose was increased to as much as 1200 mc.d., and definite improvement was noted in several instances. Two cases of proved carcinoma are alive and free from symptoms after more than four years.

Carcinoma of the cervix.—One hundred cases were divided into two similar groups of 50 each. One group was treated by deep X rays working on a potential of about 200 kv., the other was treated by radium at a distance. The same local treatment was used in both cases. No difference whatever in the results was noted. Of Class I. (early cases) the percentage free from symptoms for five years was 83, whilst in Class III. (advanced cases) the percentage was 34.

Prof. Regaud regards deep X rays as the established method, and radium at a distance as an interesting and hopeful experiment. He considers it of great importance that far larger amounts of radium should be used. He has arranged for the 4-gramme unit at present in use to be increased almost immediately to 8 grammes, and in conjunction with Murdoch, Forssell, Holthusen, and Morison for the provision of a 15-gramme unit at Brussels. He is not, however, convinced that developments in X ray apparatus, and the raising of the potential to perhaps a million volts, may not again place X rays at an advantage as compared with radium.

Dr. Lacassagne, assistant director to the Institut, regarded as of extreme importance in treatment the accurate orientation of the unit, and the limitation of the period of treatment to the tolerance of the patient. It was impossible, he thought, to treat two patients at the same time satisfactorily. Neither Regaud nor Lacassagne regarded the very wide field exposed in their unit as in any way dangerous; it enabled them in fact to treat a larger volume of tissue. It did not involve any special danger to the liver, spleen, kidneys, or pancreas; a case of carcinoma of the liver had been treated with success, and without untoward result, the patient being alive four years later. They regarded the skin as one of the most sensitive structures in the body, and the arrangement of their treatment was largely directed to its protection.

At the Hospital, 33 rue Antoine Chantin, where the 4-gramme radium unit is situated, Dr. Monod explained the method of using it and of charting the treatment.

The unit is chiefly employed for the accessory treatment of carcinoma of the cervix, and in most cases the course of treatment extends over 21 days, during which the patient receives the radiation from 2100 mc.d. The aperture of the unit is 150 sq. cm., and in every case the treatment is given with the radium at a distance of 10 cm. from the skin. For the first two weeks the period of treatment is three hours on each day, but in the fourth week this is increased to four hours. The exposures are made through seven distinct portals in rotation, so that the same portal is not employed again until after the lapse of a week. The unit will shortly be increased to 8 grammes, without altering the mounting or screening.

A visit was also paid to the suburban Anti-Cancer Centre at Villejuif, 14 Avenue des Ecoles, where a 2-gramme is used as an accessory to local treatment, and chiefly in carcinoma of the cervix. Exposures varied with the tolerance of the patient; in most instances two exposures a day were given varying between two to four hours each. Dr. Wickham expressed himself as satisfied with the results.

VISIT TO STOCKHOLM

At Radiumhemmet, Dr. Ellis Berven, director of the Institute, demonstrated some twenty cases of carcinoma of the mouth and pharynx treated by the following technique: (1) primary treatment with the unit, (2) removal of any remaining growth by endothermy, and (3) final treatment by surface application of radium element. In the more recent cases the success of the treatment by the unit had been so considerable that no other procedure had been required. Among the cases were:—

A woman of 54, treated five years ago for sarcoma of the right tonsil. No recurrence, and the only trace of treatment slight scarring of the anterior pillar of the fauces.

A man of 62 with carcinoma of the right tonsil invading the back of the tongue, with large secondary masses in the neck. This man was treated three years ago by the unit only. No trace of any growth was discoverable, and beyond extensive scarring and telangiectasis in the neck, and some scarring of the tonsillar region, there was no evidence of previous disease.

A man of 52 with carcinoma in the left floor of the mouth extending far back towards root of the tongue, with a small secondary gland. There is now no trace whatever of disease.

A man of 65 with an extensive carcinoma actually infiltrating the greater portion of the left lower jaw. Six months ago this man was treated exclusively with the unit. The surface had healed entirely, excepting for a small area of necrosis where the dead bone had not yet separated.

The great bulk of the cases were inoperable when first seen, and most of them might have been regarded as surgically impossible, even from the point of view of alleviation. Dr. Berven admitted a certain percentage of failures. The unit was applied in general through an average of six ports of entry, arranged so as to provide full concentration on the tumour, but to avoid injury to the skin. With the exception of one or two cases where fixed glands had demanded an excessive local dose there was no trace of skin reaction.

Prof. Rolf Sievert, who designed the unit, demonstrated its construction.

It consists of a heavy mass of lead arranged in the form of the letter L, and pivoted about the middle of the longer limb. The radium itself is contained in a flat carrier, which can be inserted into either of two slots placed near the extremities of the two limbs of the L. The box contains 60 tubes of 50 mg. of radium element each, making 3 grammes in all, and it is so arranged that these tubes can be concentrated at the centre or brought out to the sides of the box by an external lever. When inserted in the short end of the unit the radium is brought into its central position. It is protected by the equivalent of 5 mm. of lead, and its distance is 6 cm. from the skin surface. The maximum aperture is a circle of 5 cm. in diameter. At the larger end the skin distance is again 6 cm., with a maximum aperture of 8 cm.

The unit is so mounted and placed as to move with the greatest facility into any position. The smaller end is used for situations where the introduction of the larger end would be anatomically impossible, such as the neck and the perineum. It has, however, a smaller lead protection, the thickness being here only 2·5 cm., as against 6 cm. at the heavy end.

Dr. Sievert also showed his new system of measuring ionisation and thereby determining the intensity of gamma rays with precision.

The essential part consists of two concentric spheres of metal insulated from one another by four points of amber. They can be of small size; in one the outer sphere was only 5 mm. in external diameter. The principle consists in charging the inner sphere to a high potential and then placing the instrument for a known time in a region to be investigated. The inner sphere is discharged by ionisation across the intervening air space at a rate proportional to the radiation, and a measurement of the charge remaining on the inner sphere enables the radiation to be determined with great exactness. These instruments have been charged in Stockholm, sent to America, there exposed to radiation, and returned to Stockholm, when it has been found possible to determine the value of the radiation to which it had been exposed within an error of 2 per cent.

In conversation Prof. Gösta Forssell expressed the opinion that with larger supplies of radium it ought to be possible to obtain even better results than those which had been shown. He saw no reason why, with sufficient quantities of radium and with sufficient experience in its application, it should not be possible to deal successfully with cancer in any region of the body. Although at present carcinoma of the intestinal tract was outside the possibility of direct treatment, he was convinced that by some combination of surgery and radium it could ultimately be brought under control. He attributed the success achieved in the Stockholm clinic to two chief factors: the combined team-work of a group of men, each expert in his own department, and the extreme precision with which the whole of their work was controlled.

THE FUTURE OF AMERICAN MEDICAL PRACTICE

(FROM AN OCCASIONAL CORRESPONDENT IN THE UNITED STATES)

AFTER five years' study the Committee on the Costs of Medical Care has published its final report. The committee is an unofficial body of doctors, public health officers, sociologists, and representatives of the general public. Its object, in the words of President Hoover, is to propose plans "for the delivery of adequate scientific, medical care to all of our people, rich and poor, at costs which can be reasonably met by them in their various stations of life."

In the authorised summary of its report the total cost of medical care for the nation in the year 1929 is *estimated* at $3,656,000,000. Attention is called to the uneven incomes of medical practitioners. The average net income of the general practitioner is found to be less than $4000, while that of the specialist is over $10,000. The expenditure of the medical dollar is made up as follows: physicians, 29·8 cents; hospitals, 23·4 cents; dentists, 12·2 cents; medicines, 18·2 cents; public health, 3·3 cents; nurses, 5·5 cents; "cultists," 3·4 cents; all others, 4·2 cents.

DEFECTS OF THE PRESENT SYSTEM

The present system of medical care is found to be deficient in nine respects:—

1. The people need a substantially larger volume of scientific medical service than they now utilise. This is particularly true of persons with small incomes. In spite of the large volume of free work done by hospitals, health departments, and individual practitioners, and in spite of the sliding scale of charges, it appears that each year nearly one-half of the individuals in the lowest income group receive no professional medical or dental attention of any kind, curative or preventive.

2. Modern public health services need to be extended to a far greater percentage of the people, particularly in rural areas, towns, and small cities.

3. There is need for a geographical distribution of practitioners and agencies which more closely approximates to the popular medical requirements.

4. Current expenditures for medical care, in rural and semi-rural areas, are insufficient to ensure even

approximately adequate service, to support necessary facilities, or to provide satisfactory remuneration to the practitioners.

5. Many practitioners, particularly well-trained recent graduates, should have opportunities to earn larger net incomes than they now receive. Incomes of general practitioners and of specialists should be more nearly equal than at present. The opportunity and incentive for "fee-splitting" should be removed.

6. Better control over the quality of medical service is needed, and opportunities should be provided for improving quality as rapidly in the future as it has been improved in the past. Improvement of the quality of service would include: Elimination of practice by unqualified "cult" practitioners; control over practice of secondary practitioners (like midwives, chiropodists, and optometrists); restriction of practice of specialties to those with special training and ability; more opportunity for post-graduate study for physicians, particularly rural practitioners; more opportunity for physicians to exchange experiences and to assist each other; better control, through supervision and further education, over the work of certain physicians and dentists who even though regularly licensed are not competent for many functions.

7. There should be more effective control over the number and type of practitioners trained, and their training should be adjusted to prepare them to serve the "true" needs of the people.

8. There is a need for reduction of waste in many directions, such as the money spent on unnecessary medication, on services of poorly qualified or utterly unqualified "cultists"; and in wastes due to idle time of practitioners, high "overhead" charges of private medical and dental practice, unused hospital accommodations, and the sending of patients from place to place for medical service.

9. There is need for some plan whereby the unequal and sometimes crushing burden of medical expenses can be distributed. The prevailing methods of purchasing medical care lead to unwise and undirected expenditures, to unequal and unpredictable financial burdens for the individual and the family, to neglect of health and of illness, to inadequate expenditures for medical care, and often to inequable remuneration of practitioners.

REMEDIES

The Committee's solution for the uneven burden of cost and the uneven rewards for service is that group service shall be rendered in return for group payment. The majority recommendations are as follows:—

1. Medical service, both preventive and therapeutic, should be furnished largely by organised groups of physicians, dentists, nurses, pharmacists, and other associated personnel. Such groups should be organised, preferably around a hospital, for rendering complete home, office, and hospital care. The form of organisation should encourage the maintenance of high standards and the development or preservation of a personal relation between patient and physician.

2. The committee recommends the extension of all basic public health services—whether provided by governmental or non-governmental agencies—so that they will be available to the entire population according to its needs. Primarily this extension requires increased financial support for official health departments and full-time trained health officers and members of their staffs whose tenure is dependent only upon professional and administrative competence.

3. The costs of medical care should be placed on a group payment basis, through the use of insurance, through the use of taxation, or through the use of both these methods. This is not meant to preclude the continuation of medical service provided on an individual fee basis for those who prefer the present method. Cash benefits—i.e., compensation for wage-loss due to illness—if and when provided, should be separate and distinct from medical services.

4. The study, evaluation, and coördination of medical service should be considered important functions for every State and local community; agencies should be formed to exercise these functions, and the coördination of rural with urban services should receive special attention.

5. The committee makes the following recommendations in the field of professional education:—

(*a*) That the training of physicians give increasing emphasis to the teaching of health and the prevention of disease; that more effective efforts be made to provide trained health officers; that the social aspects of medical practice be given greater attention; that specialties be restricted to those specially qualified; and that post-graduate educational opportunities be increased.

(*b*) That dental students be given a broader educational background.

(*c*) That pharmaceutical education place more stress on the pharmacist's responsibilities and opportunities for public service.

(*d*) That nursing education be thoroughly remoulded to provide well-educated and well-qualified registered nurses.

(*e*) That less thoroughly trained but competent nursing aides and attendants be provided.

(*f*) That adequate training for nurse-midwives be provided.

(*g*) That opportunities be offered for the systematic training of hospital and clinic administrators.

MINORITY RECOMMENDATIONS

The principal minority report is signed by nine members. Since it may be said to represent the official viewpoint of the American Medical Association it is also given here in full.

1. The minority recommends that government competition in the practice of medicine be discontinued and that its activities be restricted (*a*) to the care of the indigent and of those patients with diseases which can be cared for only in governmental institutions; (*b*) to the promotion of public health; (*c*) to the support of the medical departments of the Army and Navy, Coast and Geodetic Survey, and other government services which cannot because of their nature or location be served by the general medical profession; and (*d*) to the care of veterans suffering from bona-fide service-connected disabilities and diseases, except in the case of tuberculosis and nervous and mental diseases.

2. Government care of the indigent should be expanded with the ultimate object of relieving the medical profession of this burden.

3. The minority joins with the committee in recommending that the study, evaluation, and coördination of medical service be considered important functions for every State and local community, that agencies be formed to exercise these functions, and that the coördination of rural and urban services receive special attention.

4. United attempts should be made to restore the general practitioner to the central place in medical practice.

5. The corporate practice of medicine, financed through intermediary agencies, should be vigorously and persistently opposed as being economically wasteful, inimical to a continued and sustained high quality of medical care, or unfair exploitation of the medical profession. . . .

7. The minority recommends the development by State or county medical societies of plans for medical care.

Two dentists have signed a separate report agreeing in most respects with the majority, while Prof. W. H. Hamilton, of Yale University, presents a private solution of his own. The million dollars provided for this study has now been spent. No money was appropriated for promotion of the plans which the committee has evolved. Nevertheless the chairman of the committee, Dr. Ray Lyman Wilbur, Secretary the Interior, who will shortly return to his non-litical position as president of Stanford University. presses the hope that a continuing organisation ay immediately be formed to promote demonstraons in local communities.

MEDICINE AND THE LAW

Nuisance by a Mental Patient

LEGAL text-books say there is no recorded case of n action of tort being brought against a lunatic. f so. some proceedings in the Barton-on-Humber ounty court (recently reported by the *Law Journal*) re of exceptional interest. Tort. it is hardly necesary to explain. is the lawyer's label for a class of wrongs and breaches of duty which. when committed by one person. are legally harmful to another. Most of the actions in the law courts are framed ither in tort or in contract; sometimes the same action has elements of both.

The Barton-on-Humber proceedings concerned the occupiers of two adjoining houses divided by a party wall. The occupier of No. 12 complained that the wife of the occupier of No. 11 banged continually on he wall night and day and for long periods at a time, and that she also screamed and shouted filthy and disgusting language. The result on the occupier of No. 12 was insomnia and nervous debility necessitating medical attention. No. 12 asked the county court judge to grant an injunction and damages against No. 11. The offender in No. 11 had been a certified lunatic; she suffered from chronic delusional insanity; a year ago she was an inmate of a mental hospital whence she was released upon her husband undertaking to look after her. Her husband was joined with her as co-defendant in the county court action because, by a feminist streak in our law. a husband is responsible for his wife's torts. But the husband here was not liable qua husband unless his wife was liable: if the wife was insane. could she be liable for a tort? According to a dictum of Lord Esher in Hanbury v. Hanbury (1892). if A does an act which, if done by a person of sound mind. would make him civilly or criminally responsible to the law. then. if the disease in A's mind is not so great as to make him unable to understand the nature and consequence of the act, that is an act for which A will be civilly or criminally responsible. This implies that lunatics are not entirely above the law. The county court judge drew a distinction between voluntary and involuntary actions. He held that the noise of the banging and screaming amounted to a nuisance in law: it was in fact a tort, an actionable wrong. If the woman knew she was doing the acts complained of. she was liable in damages. The judge held that, although insane. the woman knew she was doing an act which annoyed her neighbours. She was in part amenable to reason. Her husband had said "She stops when I tell her." There was evidence that on one occasion. after a letter from the plaintiff's solicitor had been read to her. she was quiet for a fortnight. She bangs. said the judge. because she thinks she is provoked; therefore she does realise what she is doing. Consequently she was legally liable for the nuisance she committed. As the husband had offered to leave the house and take his wife away elsewhere. the judge might have been reluctant to grant the remedy of an injunction because that remedy is not deemed appropriate if there is no threat or prospect of future and continued infringement of rights. As. however. the nuisance had now been going on for years. an injunction was granted and. in addition. damages to the amount of £5 were awarded.

Noise as an Actionable Wrong

The foregoing case must not be taken as indicating that all noise from neighbours is a nuisance in law. Judges have made it clear that people who live in towns must expect the kind of noise which is inseparable from collective life. A convenient summary of the law is to be found in the judgment of Luxmoore, J., in Vanderpant v. Mayfair Hotel Co. (1930). a case where a resident in Curzon-street complained of the noise arising at the hotel from shouting, loud talking. or the handling of kitchen or domestic utensils. milk churns and other articles—noise which reached a climax when the preparation of meals was in full swing. The judge observed that. apart from any right which may have been acquired against them by contract. grant. or prescription. people are entitled as against their neighbours to the comfortable and healthy enjoyment of the premises they occupy. In deciding whether. in a particular case. this right has been interfered with and a nuisance thereby caused, it is necessary to determine whether the act complained of is an inconvenience materially interfering with the ordinary physical comfort of human existence. not merely according to elegant or dainty modes and habits of living but according to plain and sober notions obtaining among English folk. It is also necessary to take into account the circumstances and character of the locality. If the noise is an actionable nuisance according to this standard. it is no answer to say that the best known means have been taken to reduce or prevent it, or that the cause of the nuisance is the exercise of a business or trade in a reasonable and proper manner. The question of the existence of a nuisance is one of degree. and depends on the circumstances of the case.

It might be added that if the ordinary law could adequately restrain the noise nuisance. it would not be necessary for particular localities to obtain special powers by local Act for controlling that nuisance. There must be plenty of medical practitioners who are aware. either by their own experience or by that of their patients. of the annoyance and the menace to health which noise can constitute.

IRELAND

(FROM OUR OWN CORRESPONDENT)

THE IRISH HOSPITALS' SWEEPSTAKES

THE second report of the Committee of Reference of the Irish Hospitals' Sweepstakes—that dealing with the Grand National Steeplechase of last March—contains criticisms of the claims of the several participating institutions. the allotment of funds as approved by the Minister for Justice. and also some general observations on hospital policy. The allotment of funds is on the same principle as in the first report. and the flaws then observed became more obvious with each additional distribution. The method followed is to consider each claim as presented. prune it of extravagances and unnecessary expenditure. and declare an "award" such as would be proper to make if unlimited funds were available. This "award" is a purely imaginary figure. It is next reduced by the sum already received from previous sweepstakes by the institution concerned. The amount actually available is then distributed in proportion to the reduced "awards" so reached. This constitutes the real award. In the sweepstake under consideration the real award stands to the reduced imaginary award in the proportion of (in round figures) 1 to 14. Two flaws appear in this method. The deduction of the sum already received should be made from the real and not from the imaginary award. The principle adopted results in much larger sums proportionally being granted to the hospitals which have been participating for the longest periods. It neglects the actual present needs. In the second place, a percentage grant towards a scheme approved by the Committee may not in fact be of any help toward the carrying out of that scheme. For example, suppose that a building or development scheme to cost £100,000 be approved. But a grant of only £7000 is available. Clearly the full scheme cannot be undertaken on such a basis, and the grant may lie fallow or may have to be applied to some other purpose. These flaws would, of course, disappear if, during the lifetime of the sweepstakes, the total amount of the imaginary awards should become available, but only on this hypothesis. Moreover, neither the Committee of Reference nor the Minister has power to ensure that any particular grant should be used for the purpose for which it is given.

In its general observations the Committee of Reference pays special attention again to the lack of coördination between the several hospitals, and in particular in the case of children's hospitals. It is suggested that the several children's hospitals in Dublin should combine to form a joint central clinic. The Committee, while suggesting coördination and coöperation in both its reports, appears to be shy of discussing amalgamation; but the question cannot be avoided, and no doubt evidence on it will be put before the Hospitals Commission which is soon to be appointed to consider the whole question of hospitals in the Irish Free State.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

THE following half-yearly promotions have been made: Surg. Comdrs. to be Surg. Capts.: W. H. Edgar, A. G. V. French, and H. E. R. Stephens.

ROYAL NAVAL VOLUNTEER RESERVE

Surg. Comdr. T. Turner to be Surg. Capt.

Surg. Lt.-Comdrs. T. W. Drummond and W. F. W. Betenson to be Surg. Comdrs.

Surg. Sub-Lt. K. E. L. Yuill to be Surg. Lt.

ROYAL ARMY MEDICAL CORPS

ARMY RESERVE OF OFFICERS

The undermentioned, having attained the age-limit of liability to recall, cease to belong to the Res. of Off.: Lt.-Cols. J. Fairbairn and R. R. Lewis.

TERRITORIAL ARMY

Lts. W. H. D. Patterson and B. Reid to be Capts.

INDIAN MEDICAL SERVICE

The prob. appt. of William Fleming as Lt. is confirmed. Capt. P. S. Varadarajan relinquishes his temp. commn.

NATIONAL ASSOCIATION FOR THE PREVENTION OF TUBERCULOSIS.—The 19th annual conference of this association will be held at Cardiff from July 13th to 15th. The address of the association is Tavistock House North, Tavistock-square, London, W.C.1.

NEW YEAR HONOURS

THE list of honours issued on Jan. 1st contains the names of the following members of the medical profession:—

Baron

Sir Thomas Jeeves Horder, Bt., K.C.V.O., F.R.C.P.
Senior physician to St. Bartholomew's Hospital; physician-in-ordinary to the Prince of Wales.

K.C.I.E.

Major-General John Wallace Dick Megaw, C.I.E., M.B., K.H.P.
Director-General of the Indian Medical Service.

K.C.V.O.

Frederic Jeune Willans, C.V.O., M.R.C.S.
Surgeon apothecary to H.M. Household at Sandringham.

Knights Bachelor

John Lawrance McKelvey, F.R.A.C.S.
Surgeon to the Royal Prince Alfred Hospital, Sydney.

San Crombie Po, C.B.E., M.D.
Medical practitioner and municipal commissioner, Bassein, Burma.

C.B.

Surgeon Rear-Admiral Herbert Reginald Harry Denny, M.R.C.S., R.N.

C.M.G.

Walter Burford Johnson, M.B., W.A.M.S.
Director of medical and sanitary service, Nigeria.

C.I.E.

Major-General William Charles Hughan Forster, M.B., V.H.S., I.M.S.
Surgeon-General with the Bombay Government.

Colonel John Norman Walker, M.R.C.P., I.M.S. retd.
Director of medical department, H.E.H. the Nizam's Government, Hyderabad, Deccan.

Lieut.-Colonel Robert Beresford Seymour Sewell, M.R.C.S., I.M.S.
Director of the Zoological Survey of India.

C.V.O.

William Hope Fowler, F.R.C.S. Edin.
Consulting radiologist to the Royal Infirmary, Edinburgh.

O.B.E. (Military)

Surgeon Commander William Harold Edgar, M.D. R.N.

O.B.E. (Civil)

John Thomas Bradley, M.D.
Chief medical officer, Seychelles.

Miss Charlotte Purnell, M.S.
Surgeon to the English Mission Hospital, Amman, Transjordania.

Eric Slack, M.B.
Medical officer, Leper Settlement, Botsabelo, Basutoland.

Robert Stanley Taylor, M.D.
Principal medical officer, Somaliland Protectorate.

Kaisar-i-Hind Medal

Miss Charlotte Rose Greenfield, M.B.
Medical officer in charge of St. Margaret's Hospital, Poona, Bombay.

Robert Harold Hull Goheen.
Medical missionary in charge of the American Presbyterian Mission Hospital, Vengurla, Bombay.

Rt. Rev. Kenneth William Stewart Kennedy, M.B.
Bishop of Chota Nagpur.

THE DOCTOR'S DAY

"Come, tell me how you live," I cried,
"And what it is you do!"

IX.—THE ANÆSTHETIST

COMPARED with other branches of practice the administration of anæsthetics has obvious advantages. One is that when the anæsthetist leaves after an operation his work is done as far as that patient is concerned; he has no worries about after-treatment or future welfare. It is true that some post-operative troubles are commonly attributed to the anæsthetic, but even so the anæsthetist's practical connexion with them is chiefly a matter of prevention. He is rarely called in to give help however much he may be made the scapegoat for its necessity. Again, the anæsthetist requires no consulting-room, so to say no shop-window. He is free to live where and as he pleases, so long as his home is not far from his base, and he can be reached at once on the telephone. Thus, provided he has someone to answer the telephone when he is out and capable of making appointments, a couple of rooms—even a good bed-sitting-room—suffice him. His expenses are far less than those of the general practitioner or of any other kind of specialist. His working-plant is no doubt a big item at the start, but to keep it in order and to supply the annual consumption of drugs, nitrous oxide, oxygen, ether, and the rest, is not a heavy burden. To practise in London he will not find a car essential; taxi-cabs are good enough. But it must be either London or some other large town; anyone who wants a country life must take up some other branch of medicine. He might perhaps live out of town if he decides to limit himself to dental anæsthetics which are required only in the day-time.

PROSPECT OF EARLY SUCCESS

An obvious advantage which the anæsthetist enjoys is that he begins to earn a fair income early in his career; he is not expected to look mature or even middle-aged. Many surgeons indeed prefer to work with an anæsthetist much younger than themselves so that they retain that sense of undisputed command and control of the entire proceedings which they think essential for the proper conduct of an operation. This advantage however of starting success early is counter-balanced by the disadvantage that an anæsthetist's work is likely to fall off comparatively early too. He is more apt to be displaced by the younger men than are workers in other branches. And this comes the harder on him as his emoluments are not high. With regard to this side of his work the anæsthetist's position is a little peculiar. Sometimes his fee is arranged by the surgeon, sometimes by the practitioner, and sometimes he is asked himself to name it. In the two former instances a common custom is for the anæsthetist's fee to be stated in terms of the surgeon's—10 per cent. as a rule. There is really no logical connexion between the two fees, and as time goes on and the true value of expert anæsthetists is more fully recognised he will more commonly be asked to state his own fee. It is obviously not easy for an anæsthetist in his active years, which are comparatively short, to save a sum sufficient to carry him on when his work is declining. It is partly no doubt for this reason that many men try to combine the career of an anæsthetist with that of a general practitioner. When their anæsthetic work falls off they have still the general practice on which to rely. Nevertheless this double life is not entirely satisfactory. The two kinds of duty often clash, and it is not easy to reach a good position in either career if both are attempted. Moreover, the tendency at the best hospitals now is to appoint as anæsthetists only those who are prepared to devote themselves entirely to this branch of work.

AN AVERAGE DAY

Let us glance at an average day in the life of a London anæsthetist attached to a teaching hospital and in the full bent of his career. At 9 A.M. he is at a nursing home to give an anæsthetic for a laparotomy performed by one of the surgeons with whom he is associated in hospital. At noon he gives gas-and-oxygen at a dentist's within a walk of his rooms, and at 12.45 P.M. another dental anæsthetic not far off. After a brief lunch he goes to hospital where he is giving anæsthetics and teaching students from 2–5 P.M. At 6 P.M. he gives an anæsthetic for an ear and throat surgeon. At 7 P.M. he pays a visit to a nursing home in order to examine a patient to whom he is to give an anæsthetic on the morrow and to decide about a preliminary injection. Some days he will have more to do than this, on others much less, and occasionally he will be wanted after dinner or at night for an emergency, an acute appendix or mastoid for example. Now and then his ordinary routine will be interrupted by a day with a maternity patient who desires to have no pain at all or has requested that an anæsthetist may be in attendance early during the confinement. Often it will happen that he receives invitations from two surgeons for the same hour, or so nearly the same that he is obliged to refuse one of them. And often it will happen that the case which he has been told will take "about half an hour" actually occupies from first to last an hour and a half. Those things make it difficult for a busy anæsthetist to arrange his work without ever being unpunctual.

HIS VARIED OUTFIT

The anæsthetist's job is nowadays not monotonous because there is such a variety of methods and drugs at his disposal. In the course of an afternoon he may be giving long gas-and-oxygen, open ether, endotracheal, gas-and-oxygen plus ether, and using spinal and regional methods. He cannot consider himself fully competent unless he can employ any one of these easily and successfully when a case demands it. Anæsthetics form no longer a narrow specialty; indeed the scope is so wide that already there are specialists within the specialty, one man for example making himself expert at endotracheal, another concentrating on spinal and regional injection. This wide choice has made more insistent the desirability of an interview between patient and anæsthetist before the operation, so that the anæsthetist can arrive at the correct decision. In hospital work this previous examination is rarely possible, and the anæsthetist must learn to make quick decisions just before operation. In private practice he is well-advised to see the patient the day or at least some hours before operation whenever this is possible, and it is remarkable how much this extra attention is appreciated. The sedative and encouraging effect of such a visit leaves the patient disposed towards a quiet entry into unconciousness.

An anæsthetist's position is peculiar in this that it is dual. He has relationship at the same time with his surgeon and with the patient and it may occur—although fortunately not often—that the line of action which he would choose in order best to please the one is not that which is for the greatest welfare of the other. What degree of anæsthesia is proper for a difficult abdominal operation? There are surgeons who insist on absolute relaxation, and there are patients in whom complete abolition of muscular tone involves grave risk. Here is a quandary to be solved only by the clear principle, to do what is believed to be in the best interests of the patient.

THE SAVOUR OF HIS CAREER

The anæsthetist's association with surgeons provides the savour of his career. Endowed with a modicum of tact and sense of humour he will derive a steady source of enlightenment and amusement from the different behaviour, professional and social, of those with whom he is privileged to work. One surgeon prefers complete silence during an operation, another talks all the time and expects audible appreciation. The anæsthetist may get salutary lessons in self-control both from the operator who occasionally loses his temper and reviles him and others, and from the surgeon who remains placid and efficient when everything appears to be going wrong. In private the anæsthetist learns diplomacy at interviews with patients' friends, and how to inspire confidence without forsaking veracity. He will not too rarely derive comfort from the surgeon's reference to the " excellent anæsthetic which Mr. A. administered." He will know how to work with those who follow every verbal appointment with a written confirmation and others who invite him to give an anæsthetic at a time and place to which a colleague has already been bidden.

It is open to any man of average attainment to become a first-rate anæsthetist if in addition to all else he is possessed of one additional quality—namely, nerve. The man who is easily perturbed and thrown off his balance can never succeed in this branch of work, for he will be confronted at times with a patient whose condition, suddenly and unexpectedly, becomes critical. His duty is then at once, without causing alarm or confusion, to see that all steps are taken to bring about recovery. There is nothing more harassing to the surgeon than an anæsthetist who is forever becoming needlessly alarmed, and nothing more dangerous than one who is not alive to the indications of approaching trouble. One other virtue is essential if he is to be acceptable to surgeons, and that is punctuality. He must never keep his surgeon waiting, and it is one of the chief difficulties with which he has to contend that surgeons are apt to prefer the same hour. It needs some strength of mind to refuse a case rather than run the risk of being late for it, but the anæsthetist who makes sacrifices in order to maintain punctuality will be repaid in the long run.

Outside his practical work he can find plenty of professional interest. There are problems of physiology and of psychology constantly arising in his daily work, and if he can make time and opportunity to seek the solution of these problems by experimental work he will add greatly to the attractions of his occupation. He will want to keep his knowledge abreast of the times by studying the periodic literature of his own and other countries. The man who is starting his career as an anæsthetist may, I think, face the future with a light heart for his work is young, as such things go, and there is plenty of development still ahead. Finality and perfection are far from having been reached in the practice of anæsthetics. He can have a full and interesting life, even if he is engaged on a career which has been well described as " honourable, but not fertile."

PUBLIC HEALTH SERVICES

Public Health in the Local Acts of 1931–32

The newly issued official Index to the Local and Private Acts [1] for the session 1931–32 has to deal with 97 Acts as against 112 in the previous session. The policy of economy must have reduced the activity of local authorities in seeking fresh powers from Parliament. Except for the Bury Corporation Act there is hardly an instance of any large-scale advance in a local code of public health. As usual, the recurrence of familiar provisions—for example, the power to close Sunday schools during epidemics—makes one wonder why Parliament is so slow to enact in a general Public Health Act many well-established common-form clauses which an individual local authority has now to pay to obtain in an Act of its own. Some Local Acts are due to a desire to alter existing rights as when St. Andrews wants power to charge a fee for admission to the golf links during championships. In the main the Local Acts represent progressive stages in eluding the restrictive influence of the district auditor and the doctrine of *ultra vires*. Though it may be a legal person, a local authority has no powers which it has not been expressly given. Does a town like Bury want to spend money on an aerodrome or on educational lectures or on pictures for its art gallery? These activities, deemed by some desirable, by others extravagant, are outside its scope until Parliament gives permission. Some local bodies set the pace for others; gradually the new powers are tested by experience and are adopted elsewhere if found successful. The following summary, as in previous years, endeavours to specify novel clauses likely to serve as precedents.

To begin with the subject of food, the London County Council breaks fresh ground. An existing provision for inspection and destruction of unsound meat, &c., is extended to animals or articles of food and drink offered as prizes at entertainments or given away under advertisement schemes or otherwise. London, Bury, and Rochdale have fresh requirements for compulsory notification of food poisoning. There are various familiar clauses for restricting the handling of food by infected persons, for registering makers and premises in respect of ice-cream or potted meat, and for the general regulation of food preparation, storage, and transport. Dundee has power to restrict the conveyance of meat in open vehicles; this power seems new in Scotland. The Bury clauses as to street vendors of food, inspection of vehicles, and precautions against contamination where food is prepared in yards follow previous precedents, but there seems to be a new safety provision requiring fire-extinguishing apparatus to be available where heated or boiling fat or oil is extensively used in cooking fish or potatoes. Again, as regards infectious disease, the Bury Act (Part VIII.) includes several well-tried provisions as to the supply of antidotes, the removal of dead bodies and the disinfection of conveyances used for carrying them, tuberculosis disinfection, powers of keeping children away from Sunday schools and entertainments, entry into premises where there is dangerous infectious disease, obtaining laundrymen's names, compulsory information "for the purpose of enabling means to be taken to prevent the spread of the disease," notification of pulmonary tuberculosis, and power to demolish stables or cowsheds when the medical officer certifies the presence of infectious or parasitic disease. A few of these clauses also appear in the Welwyn Garden City Act.

In respect of housing and building law the Bury corporation seems to have struck out a new line by prohibiting the construction of cellars or rooms belonging to dwelling-houses where the floor level will be below the highest known level of subsoil water. It also restricts the erection of dwelling-houses on land which is either liable to flooding or unsuitable by reason of the nature of the subsoil. With an unhappy experience of the danger of floods to houses and their occupants, the London County

---

[1] H.M. Stationery Office. 1s. 6d.

Council has taken new powers to maintain automatic tide gauges and to give warnings of high tides in the Thames. Rochdale, Blackpool, and Wolverhampton have elaborated their powers of regulating buildings, though not all have so large a scope for by-laws as at Bury, where the corporation may regulate the number of houses in one block or row, the intervening spaces, height of walls or fences, testing of drains, adequate flushing of closets and protection of their pipes from frost, fixed baths, ventilation of geysers. Bury has also the usual provision as to food storage accommodation in existing and future dwelling-houses (ventilated pantry and other facilities). Provisions which perhaps affect amenities more than health include the Edinburgh restriction on "ribbon" building development along roads (Surrey furnished a precedent for this last year) and the Bury clause for removing dilapidated and neglected buildings which are "in a structural condition prejudicial to property in, or the inhabitants of, the neighbourhood." There is a novel clause in the Edinburgh Act for requiring repainting or redecoration of exteriors. Cities like Bath, which have panoramic assets to be destroyed, will doubtless note this attention to colour-schemes. A wide range of clauses controlling the lay-out of land and the erection of temporary structures occurs in the Lindsey County Council (Sandhills) Act, where doubts about the ownership of the Sandhills and the power to enclose or build have been solved in special circumstances. The Act recites that many buildings "are unsightly or otherwise of an undesirable character . . . and are not provided with a proper water-supply or sanitary conveniences." Fresh provision for regulating life in tents, vans, and shacks is made at Rochdale, Welwyn, Bury, Cambridge, and Clydebank. Dundee has provided for an equalisation fund for slum clearance. At Birkenhead abandoned drains must be filled in, and persons constructing new streets may be required to provide separate sewers for sewage and for surface water.

There is less than usual of interest to the medical profession in the miscellaneous contents of the Local Acts of 1931–32. Three clauses in the Bury Act deal with nuisances encountered in town life. The nuisance of noise is added to the nuisances in the Public Health Act and is dealt with as in precedents in which Edinburgh led the way in 1930. The ejection of steam or waste gas to the annoyance of the public is prohibited. Silencers must be fitted to stationary internal combustion engines. In all three cases there is a saving for railway companies. The nuisance of dogs fouling pavements is dealt with at Edinburgh; experience elsewhere shows that this statutory provision has more value as a warning notice than in actual enforcement by penalty. An illustration of the local variety of criminal offences is the regulation at Dundee of writing or chalking on carriage-ways. Rochdale follows former precedents in restricting the sorting of the contents of ashbins. Welwyn and Bury can now require owners or occupiers of houses or shops to provide portable dust-bins. Bury has gained the power, novel until a few years ago, to remove to an infirmary any person who is aged or infirm or physically incapacitated and who lives in insanitary premises or anyone who is suffering from grave chronic disease and is not properly looked after The not uncommon precautions against plumbism appear in the Chesterfield and Bolsover Water Act. Birkenhead is now authorised to construct, equip, and manage "medicated and other baths, including baths the efficient properties of which are due to agencies other than water." To conclude this list of miscellaneous items, mention may be made of the special superannuation clause for the medical officer in charge of mental services in Edinburgh and the variation of the charitable trust of Epsom College, once known as the Royal Medical Benevolent College. The R.S.P.C.A. is incorporated by a special Act; one of the functions of its council is "to arrange for the proper conduct of punitive, persuasive, educational. Parliamentary. and all other operations."

As regards the form and draftsmanship of the Local Acts, there are two instances of successful consolidation —the Edinburgh Act and the Thames Conservancy Act. The latter contains wide powers for controlling the passing of sewage, refuse, oil. and tar into the river, and for regulating the sanitary arrangements of vessels and the general navigation of the upper Thames with special care for its bird life, its fish, and its amenities. Most of these clauses are an improved restatement of the effect of former statutes. The London County Council, which is credited with most laudable ambitions in the direction of rewriting the various laws by which its administration is carried on, has no fresh instalment in the past session. It has already consolidated the London Building Acts and is understood to be applying the same admirable effort to the various Public Health (London) Acts. The result may appear next session. It would be an object-lesson to Parliament to rewrite in orderly form the Public Health Acts applicable to the country as a whole.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED DEC. 24TH, 1932

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox. 16 (last week 28); scarlet fever, 2005: diphtheria, 882; enteric fever, 36; acute pneumonia (primary or influenzal). 1721; puerperal fever. 38; puerperal pyrexia, 94; cerebro-spinal fever. 26; acute poliomyelitis, 8: acute polio-encephalitis. 1; encephalitis lethargica. 6; dysentery. 4; ophthalmia neonatorum. 61. No case of cholera, plague. or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on Dec. 27th–28th was as follows:—Small-pox, 63 under treatment, 0 under observation (last week 67 and 1 respectively); scarlet fever, 1852; diphtheria, 1696; enteric fever, 12; measles, 251; whooping-cough. 440; puerperal fever, 21 (plus 8 babies); encephalitis lethargica. 228; poliomyelitis, 5: "other diseases," 183. At St. Margaret's Hospital there were 11 babies (plus 5 mothers) with ophthalmia neonatorum.

Deaths.—In 117 great towns, including London. there was no death from small-pox. 2 (0) from enteric fever, 24 (0) from measles. 11 (1) from scarlet fever, 20 (8) from whooping-cough. 25 (4) from diphtheria. 50 (11) from diarrhœa and enteritis under two years. and 120 (8) from influenza. The figures in parentheses are those for London itself.

Bristol and Poole each reported 1 death from enteric fever. Measles caused 5 deaths at Liverpool. and 4 at Birmingham. Four fatal cases of diphtheria occurred at Hull. Fatal cases of influenza were reported from 40 great towns, the largest number of deaths being 30 at Birmingham, 9 at Sunderland. 8 at Liverpool, 5 each at Newcastle-on-Tyne and South Shields. In the same week Glasgow reported 86 deaths from influenza and 15 from whooping-cough.

The number of stillbirths notified during the week was 277 (corresponding to a rate of 47 per 1000 total births), including 42 in London.

PANEL AND CONTRACT PRACTICE

The Out-patient Inquiry

A FIRST impression on the report of the committee appointed to inquire into out-patient methods is that most of the conclusions and recommendations are sound enough from a general practitioner's point of view, though it is regrettable that no practitioner joined in their deliberations. The committee state that it is highly desirable that in any plans for the organisation of the medical service of the community the sympathy of practitioners as well as of the hospital staff should be secured. With regard to panel practitioners, some evidence was given—we are not told by whom—that conditions of insurance practice do not make for efficiency, and that panel doctors do not give adequate time and attention to their patients, having too many of them. On the other hand, some hospital consultants, giving evidence on behalf of the B.M.A., said that all their experience showed that the great bulk of panel practice was carried out honestly and with very great skill, and they did not think that hospitals need do the work of the panel doctors for them. The committee say that the representatives of the London public medical service made out a strong prima facie case for the proposal that hospitals should refer patients to the public medical service for the treatment of minor ailments. It is suggested that, as a check on practitioners referring unsuitable cases to hospitals, each hospital should keep a record of patients referred by each panel doctor; if any doctor is found to be sending up a disproportionately large number of cases—especially if his forms were badly filled in—he should be reported to the panel committee to be dealt with.

Much evidence has been taken, some of it being mutually contradictory. The committee appear to have sought a middle way in their suggestions for solving the more important issues, such as whether a hospital should throw its doors open to everyone or offer a purely consultative service. They consider that the movement towards more consultative use of facilities is in the right direction, but that it should be possible for patients who desire a second opinion to have access to hospitals without having first to obtain sanction from a practitioner. It would indeed be difficult to refuse to see anyone who comes to hospital complaining of being ill and goes to the casualty department. One examination and one treatment is often all that is required by such a patient, but this hardly applies to out-patient attendance. The condition laid down for such attendance is inability to pay consultant fees. Nothing is said about practitioners' fees, and this is perhaps a weak spot in the report, for it implies that consultants are to be protected from loss of fees by the use of the out-patient department, but not general practitioners. The committee may be criticised for a ruling which will bolster up the whim of a patient who imagines that his own doctor cannot look after him properly, while failing to protect that doctor from loss of fees. But all will welcome the encouragement of coöperation with other agencies in the disposal of patients not suitable for enrolment as out-patients, the hospital almoner providing a valuable part of the machinery for such coöperation. Standard hospital letters are advocated.

On the question of the time spent by patients in waiting, it is pointed out that a few minutes saved by up-to-date methods for dealing with each patient in a queue makes a great difference to those at the end of the queue. For example, registration by a modern system of filing and indexing saves much time. A certain amount of waiting is inevitable, but alteration of times of attendance for old patients or groups of patients, and sometimes structural alteration can materially lessen the waiting period. Some striking instances are given in the report of minor alterations in procedure or structure which have greatly diminished waiting periods. An interesting piece of evidence was that those hospitals which by adopting new methods had reduced the waiting period, in this way attracted more patients, and overcrowding soon became re-established. In this matter of waiting the committee say "it is the consultant the patient wants to see and for whom he is willing to put up with long waiting without complaining."

The investigation of complaints elicited a statement from one witness that it is not to the advantage of a patient to become known to the hospitals as a complainer. It is agreed that complaints are not numerous.

The figures of 12 teaching hospitals show that in 1931 there were 125,000 less out-patients than in 1911, but 1,160,000 more attendances, indicating that more serious cases were being dealt with. The Hospital Saving Committee say in their evidence "one thing is common to all the hospitals—they have the confidence of the working-class population."

Psychotherapy under the Act

The position of psychotherapy under the National Health Insurance Act was carried one stage further at the last meeting of the London insurance committee when there took place a full dress debate on the question as to whether this was a treatment for which it would be legitimate for an insurance practitioner to charge fees to an insured person. It will be remembered that the Local Medical Committee for London held the view that this was a specialty which should be regarded as outside the Act; the medical benefit subcommittee of the London insurance committee thought otherwise, and on Dec. 22nd the full insurance committee for London confirmed the medical benefit subcommittee's view. Dr. Gregg led the attack against this opinion that psychotherapy should be included among the ordinary services of a practitioner to his panel patients. He asserted that the real reason underlying the unwillingness to acknowledge claims for special fees for psychotherapy was that members of the medical benefit subcommittee viewed psychotherapy with suspicion. It was, however, a definite specialty, the doctor claiming fees in the four cases on which the matter had arisen had satisfied the regulation as to his qualifications, and therefore whether the committee liked it or not they ought to pass these claims. Dr. Chase agreed that psychotherapy was a specialty and that the panel practitioner in question had the necessary qualifications, but considered that skill in psychotherapy corresponded to a high degree of specialism on the medical side of practice, such as the special treatment of diabetes, or pneumonia, or some nervous diseases. The treatment of such medical cases would not, he thought, for one moment be considered outside the scope of the Act, and yet they often involved specialist work. Whilst the treatment of diabetes would not be considered outside the Act, the moment manual dexterity was involved, such as the estimation of the blood-sugar of such a patient, both committees would agree that a charge could be made. No manual dexterity was involved in the treatment of a patient by psychotherapy, and he thought the specialty was not one for which it would be proper to charge an insured person. He held that it was obviously better to let the Ministry of Health decide the point. Miss Samuel held that nothing should be done to prevent the poor from obtaining benefits available to the rich and that the committee should do nothing to discourage the psychotherapist. Dr. Cardale spoke strongly in favour of psychotherapy being placed outside the Act, since it was now recognised everywhere as a definite specialty. Mr. T. B. Layton pointed out that the tendency of modern medical education was to give students some knowledge of every branch of medicine. Psychotherapy was not a new subject and all practitioners employed it either knowingly or unknowingly in the treatment of their patients.

The debate was continued by other speakers, till finally Mr. Spearing, the chairman of the medical benefit subcommittee, pointed out that automatically the decision to refuse payment for fees claimed for this "specialty work" made it obligatory on the Ministry to appoint a court of referees to decide the question. He did not think that it should be left to patients, needing any form of treatment, to decide whether they should go to some hospital where they would not be charged for it or whether they should pay a doctor, who hoped to cure them by this treatment, but required a fee for it. It was the duty of the committee to protect the insured person against the unscrupulous doctor. After all, the fact that he could not charge his insured person for this treatment need not prevent the doctor from giving the treatment if he was so certain that it would do good.

CORRESPONDENCE

GASTROSTOMY VERSUS INTUBATION

To the Editor of THE LANCET

SIR,—In your issue of Dec. 31st (p. 1434) Mr. Hugh Donovan makes a very moderate plea in favour of gastrostomy in cases of carcinoma of the œsophagus. The condition, practically always fatal, is regrettably frequent; many of us have at one time or another to advise a patient as to the best prospects of relief. I am prompted to offer in tabular form the pros and cons of gastrostomy and intubation.

GASTROSTOMY: *Advantages.*—(1) The operation requires no special preparation, equipment, or technical experience, but can be performed by anyone accustomed to abdominal surgery; and, if necessary, under local anæsthesia.

(2) Once a gastrostomy has been performed nutrition is assured; further surgical treatment is seldom needed. But a gastrostomy is not necessarily permanent, and can be closed if the need has passed.

(3) It is applicable to all types of stricture, and is the *only* method available where a bougie cannot be passed through the stricture.

(4) The growth is relieved from irritation, and some improvement in swallowing occasionally follows.

Disadvantages.—(1) Food is not taken by the natural channel, and is not tasted. The psychic effect, when the patient realises that he will never taste or swallow anything again, is often very bad.

(2) Swallowing even of saliva may be impossible, with resultant distress and choking from overflow into the trachea; it is not easy to nurse a gastrostomy patient in the prone or semi-prone position. (Salivation is often a prominent symptom.)

(3) With rare exceptions, only sedentary work is possible.

(4) The majority of hospital-class patients are unable to make their own arrangements for feeding, care of the fistula, &c., and so the few remaining months of life must be passed in an institution.

(5) The immediate mortality is considerable.

INTUBATION (e.g., with Souttar's tube): *Advantages.*—(1) The patient is hardly conscious of disability; he can carry out even hard manual labour, as long as his strength allows; he takes his food and drink by the natural channels, and is not bothered by saliva; the necessary modifications of diet are within the capacity of any working-class home.

(2) Intubation is readily combined with radium or radon treatment.

(3) The immediate mortality is low (? 2–3 per cent.).

Disadvantages.—(1) Special equipment and training are necessary; the greatest care and gentleness are required in dealing with the diseased gullet; a general anæsthetic or basal narcosis is usually required.

(2) Occasionally an indiscretion in diet may lead to the tube being blocked. The tube may become displaced; in experienced hands this is rare, except with a soft growth through which the tube gradually passes. Further endoscopic treatment becomes necessary.

(3) The position of the growth (e.g., at the cardia) may render it unfavourable for intubation; it may be impossible to pass a bougie through the stricture or to dilate it sufficiently to admit a tube.

Either method may be combined with deep X ray or with chemotherapeutic treatment. Whichever is adopted, one class of patient presents a very bad risk—namely, those suffering from actual water-starvation; before anything is done, measures must be taken to remedy this, and when that has been achieved, I believe intubation to be much less risky than gastrostomy. Every case must be considered on its own merits; but in general the advantages of intubation are so great, and its disadvantages so much less serious than those of gastrostomy, that this method will be preferred.

I am, Sir, yours faithfully,

E. WATSON-WILLIAMS.

Clifton, Bristol, Dec. 31st, 1932.

To the Editor of THE LANCET

SIR,—Mr. Donovan gives the records of an important research into the operative mortality-rate, average length of stay in hospital, and the duration of life after operation in a series of 47 cases of carcinoma of the œsophagus which were subjected to gastrostomy. He states that "a consideration of these results does not encourage one to advise this operation strongly"; he is impressed by the observation "that a patient has a more comfortable end when he has a gastrostomy," and that "repeated intra-œsophageal instrumentation is very distressing to some old patients." Without wishing to detract in any way from the value of the facts set forth in

MEDICAL NEWS

University of Oxford

On Dec. 17th the following degrees were conferred:—

D.M.—A. J. Gibbs.

B.M.—J. R. Robertson, R. F. Woolmer, W. H. Owles, H. B. Morris, R. C. MacKeith, R. A. Beaver, J. E. Jenkins, A. J. Grace, and N. P. Bruce.

University of Cambridge

At recent examinations the following were successful:—

THIRD EXAMINATION FOR M.B. AND B.CHIR.

Part I., Surgery, Midwifery, and Gynæcology.—J. C. G. Anderton, E. F. Baines, H. Barcroft, G. F. Barran, C. G. Batty-Smith, W. T. C. Berry, C. E. Bevan, E. V. Bevan, R. W. Billington, G. O. Brooks, R. H. Brown, J. R. Chambers, A. H. Charles, F. H. Coleman, J. Collinson, P. T. Cooper, A. G. Cross, H. S. Davis, L. W. B. Dobbin, J. R. Duffield, D. K. Emery, W. G. Evans, A. A. G. Flemming, P. H. R. Ghey, P. R. Goodfellow, R. W. Graham-Campbell, S. J. Hadfield, B. P. Harris, F. G. Hinks, M. I. A. Hunter, T. B. Jones, A. H. Knowles, D. Kyle, R. C. Langford, C. A. Lewis, W. Lewis, T. E. S. Lloyd, M. W. Lloyd Owen, K. Lumsden, F. D. MacCarthy, A. B. MacGregor, W. S. McKenzie, F. G. Maitland, T. C. Maling, G. J. H. Maud, J. W. Maycock, M. P. Morel, C. W. Morley, H. J. V. Morton, T. P. Mulcahy, J. P. S. Peck, K. M. A. Perry, F. W. J. Platts, J. S. M. Pringle, S. A. Propert, P. J. Richards, W. F. Richards, F. Ridehalgh, I. G. Robin, K. Robson, G. Scott, E. P. Sharpey-Schafer, D. W. Smithers, J. G. C. Spencer, T. V. Tattersall, A. C. Taylor, E. W. Taylor, H. B. Tipler, G. E. H. Tisdall, G. I. Watson, W. E. Wells, C. J. G. White, A. Willcox, J. Wilson, and R. M. Yeo.

Part II., Physic, Pathology, and Pharmacology.—S. E. Birdsall, C. P. F. Boulden, A. Bowen-Davies, E. Bradbury, W. D. Brown, J. W. Campbell, C. A. Clarke, F. J. Curtis, S. F. L. Dahne, W. D. Dick, L. W. B. Dobbin, P. M. Dobbs, R. H. Dobbs, J. C. Drury, G. A. Emmerson, R. H. Foster, D. W. C. Gawne, W. G. Gill, C. A. Grove, G. W. Hall-Smith, E. R. Hargreaves, B. P. Harris, J. Howell, N. M. James, H. V. Knight, A. R. R. Le Fleming, R. S. Lewis, G. A. Mandow, A. R. R. Mears, D. A. Metcalf, G. A. Miller, F. H. Morrell, J. Parkes, E. B. Pawson, R. V. Payne, K. M. A. Perry, R. G. Pulvertaft, C. G. Roberts, R. D. Roper, F. W. Shepherd, S. K. K. Sze, C. W. Thomas, C. B. M. Warren, J. G. Warren, G. D. Wedd, H. D. White, G. A. W. Whitfield, and W. Wilson.

University of London

At a recent examination the following were successful:—

M.S.

Branch I. (Surgery).—O. V. Lloyd-Davies and E. G. Muir (University Medal), Middlesex Hosp.

Forthcoming Lectures.—Six lectures on Factors in Nutrition will be given in the physiological department of Bedford College, Regent's Park, N.W., by Prof. S. J. Cowell, at 5 P.M. on Wednesdays from Jan. 11th to Feb. 15th inclusive. At the same time on Thursdays from Jan. 12th to Feb. 2nd Prof. R. J. S. McDowall will deliver a course of lectures on the Integration of the Circulation. These lectures will take place at King's College, Strand, W.C. The Respiratory Functions of the Blood will be the subject of four lectures which Dr. L. E. Bayliss will give at University College, Gower-street, W.C., at 5 P.M., on Mondays and Fridays from Jan. 16th to 27th. Prof. John Mellanby will take the chair at the first of the two lectures which Sir Charles Sherrington will give at University College on Jan. 30th and Feb. 6th at 5.30 P.M. On Jan. 30th Sir Charles will speak on the Flexibility of Reflex Action, and on Feb. 6th on the Spinal State. There will be cinematographic illustrations of the second lecture. Prof. Max Bergmann, of Dresden, will give three lectures on the Chemistry of Proteins at University College Hospital medical school at 5.15 P.M. on Jan. 20th, 23rd, and 24th. No ticket is required for these lectures.

Society of Apothecaries of London

At recent examinations the following were successful:—

Surgery.—J. L. Bates, Guy's Hosp.; A. E. Glanvill, Univ. of Birmingham; J. Harris, Univ. of Witwatersrand and Middlesex Hosp.; C. A. Saggoo, King's Coll. Hosp.; and L. Wailer, Guy's Hosp.

Medicine.—W. E. P. Corbett and F. M. F. Forrest, St. Mary's Hosp.; M. F. Levick, Univ. of Sheffield; E. M. F. O'Donovan, Royal Free Hosp.; and J. C. Selnes, Univ. of Oslo and Charing Cross Hosp.

Forensic Medicine.—M. F. Levick, Univ. of Sheffield; C. W. O'Donoghue, London Hosp.; J. C. Selnes, Univ. of Oslo and Charing Cross Hosp.; M. Sourasky, Charing Cross Hosp.; and E. Teplitzky, Univ. of Berne and St. Mary's Hosp.

Midwifery.—L. Bhanot, Royal Free Hosp.; P. D. Bhatt, London Hosp.; E. L. Burgess, King's Coll. Hosp.; W. H. Ekin, Univ. of Cambridge and Westminster Hosp.; A. J. McGuire, Univ. of Manchester and Charing Cross Hosp.; J. C. Selnes, Univ. of Oslo and Charing Cross Hosp.; and T. B. Smith, St. Mary's Hosp.

The following candidates, having completed the final examination, are granted the diploma of the Society entitling them to practise [illegible] d midwifery: J. L. Bates, P. D. Bhatt, F [illegible] arris, M. F. Levick, C. A. Saggoo, J. C. Sel [illegible]

Lectures on Primitive Man

The Swiney lectures on geology will this year be devoted to Primitive Man, and are being given in the lecture theatre of the Imperial College of Science, Exhibition-road, South Kensington, London, S.W., at 5.30 P.M., on Mondays, Wednesdays, and Fridays, by Mr. T. M. Finlay, D.Sc. The series of 12 lectures began last Wednesday; admission is free; and the programme may be had from the director of the British Museum (Natural History), Cromwell-road, S.W.7.

Royal Sanitary Institute

A joint meeting of this institute with the food group of the Society of Chemical Industry will be held at the institute (90, Buckingham Palace-road, London, S.W.), at 5.30 P.M., on Friday, Jan. 20th, when Mr. E. B. Hughes, F.I.C., of Messrs. J. Lyons and Co., will open a discussion on Factory Cleanliness in the Food Industry. The speakers will include Dr. Thomas Carnwath, Lieut.-Colonel Gerald Leighton, M.D., Dr. Charles Porter, Sir Weldon Dalrymple-Champneys, M.D., and Dr. T. W. Naylor Barlow.

Congress on the Care of Children

A Congrès International pour la Protection de l'Enfance will be held in Paris from July 4th to 9th, 1933. The main subject of discussion will be the relation between Charity and the State. The eight sections of the congress will be devoted to maternity, early childhood, late childhood, adolescence, abnormal childhood, social service, legal rights of the child, and lastly to questions of maternal and child welfare not included under any of these headings. Particulars may be had from the secretariat at 26, Boulevard de Vaugirard, Paris, XV.

German Society for the Study of the Circulation

The sixth annual meeting of the Deutsche Gesellschaft für Kreislaufforschung is to be held at Würzburg from Sunday, March 5th, to Tuesday, the 7th, when Prof. E. Magnus-Alsleben will preside. The subject chosen for discussion is the relation of the circulation to the nervous system, the first day being given up to the theoretical side, chairman Prof. H. E. Hering (Cologne), the second to clinical observations, chairman Prof. F. Kauffmann (Berlin). Anyone wishing to give papers or demonstrations should give notice before Jan. 15th to Prof. Magnus-Alsleben, Medizinische Poliklinik, Würzburg. The meetings will be held in the University Ophthalmic Clinic, Röntgenring 12.

Post-graduate Courses in Berlin

International medical post-graduate courses are to be held in Berlin on the following subjects: internal medicine (Feb. 27th to March 4th); practical hæmatology (March 6th to 11th); diseases of the skin and venereal diseases (March 20th to April 1st); practical improvements in radiotherapy (April 2nd to 9th); and surgery (April 24th to 29th). Monthly courses on all special fields of medical science, including practical work, will also be held. Arrangements are being made to hold a further series in the autumn of 1933, dealing with the following subjects: endocrinology, thoracic surgery, malignant disease, narcosis, the theory of colloids, diseases of children, ophthalmology, heredity, and orthopædics. Particulars of all these courses may be had from the information bureau of the Kaiserin Friedrich-Haus, Robert Koch-Platz 7, Berlin, N.W.7.

Fellowship of Medicine and Post-Graduate Medical Association

A demonstration of selected cases of general medical and surgical interest will be given at the Lambeth Hospital on Friday, Jan. 13th, at 2 P.M. A series of lectures on Practical Problems in Medicine and Surgery will be given on Tuesdays at 4 P.M. at the Medical Society of London, 11, Chandos-street, Cavendish-square, W., beginning on Jan. 17th. A demonstration of X ray films will also be given there by Dr. Peter Kerley on Friday, Jan. 20th, from 4.30 to 6 P.M. Three-quarters of the time will be devoted to chest and heart, and one-quarter to the intestinal tract. A course in cardiology, occupying the whole of each day with demonstrations and lectures, will be given at the National Heart Hospital from Jan. 16th to 27th. It is hoped to arrange a demonstration of cases dealing with Diseases of Children on Thursday, Jan. 26th, at 8 P.M., at the National Temperance Hospital, Hampstead-road. The demonstration will be of a practical nature, and two physicians and one surgeon will be in attendance with suitable cases which the post-graduates will be enabled to examine. Other forthcoming courses include dermatology, gynæcology, diseases of chest, antenatal treatment, &c. Application for further particulars should be made to the Secretary of the Fellowship at 1, Wimpole-street, W.1. The above courses and demonstrations are open only to members and associates.

Hunterian Society

The Hunterian lecture of this society will be delivered at the Cutlers Hall, Warwick Lane, London, E.C., at 9 P.M. on Monday, Jan. 16th, by Dr. Einar Thomsen, of Copenhagen. His subject will be Experimental and Clinical Studies of Gastric Juice.

The annual dinner will be held at the May Fair Hotel, Berkeley-street, W., on Thursday, Feb. 9th.

Royal Institution

The programme of lectures to be delivered between now and Easter include Friday evening discourses on the Crystals of the Living Body, by Sir William Bragg (Jan. 20th), on the Physical Nature of the Nerve Impulse, by Prof. A. V. Hill (Feb. 10th), and on Mind and Man, by Prof. G. Elliot Smith (March 24th). Among the courses of lectures to be held in the afternoons is one on Recent Advances in Genetics, by Prof. J. B. S. Haldane, and one on the Evolution of the Mind, by Prof. Elliot Smith, beginning respectively on Jan. 19th and March 16th.

Institute of Medical Psychology

A lecture on Occupational Therapy, followed by a demonstration of the various methods by which it can be applied to physical and mental illness, will be given at the new premises of this institute, 6, Torrington-place, London, W.C., at 3 P.M. on Saturday, Feb. 4th. Twenty lectures (for members of the medical profession only) on Psychological Types and Mechanisms, forming an introductory course of psychological medicine for practitioners, will be given on Wednesdays, from Jan. 18th to March 22nd. The lecturers will be Dr. E. Graham Howe (3 P.M.) and Dr. H. Crichton-Miller (4.30 P.M.). Tickets for the lecture and for the course should be obtained in advance from the honorary lecture secretary of the institute.

National Smoke Abatement Society

This society has sent to 130 local authorities a memorandum suggesting the establishment of further regional advisory committees similar to those which have for some time operated in greater London, the Midlands, the West Riding of Yorkshire, and the Manchester districts. It is suggested that local authorities should coöperate to form five new areas for Tyneside, Tee-side, North East Lancashire, Merseyside and South West Lancashire, and the Potteries. The existing advisory committees, which were formed with the assistance of the Ministry of Health, are endeavouring to secure greater uniformity in the administration of the law relating to the emission of smoke. Even greater importance is, however, attached to the preventive than to the punitive side of the work. The committees already in operation include among their activities the standardisation of methods of taking observations, the encouragement of training courses for stokers, and the issuing of certificates for efficiency, the encouragement of better relations between local authorities and manufacturers, and the collection of data respecting the latest developments in smoke prevention apparatus and appliances.

Births, Marriages, and Deaths

BIRTHS

LAWRENCE.—On Christmas Day, 1932, at Ivanhoe, Old Stratford, Northants, the wife of Dr. E. D. Lawrence, of a daughter.

ROTHERY.—On Jan. 2nd, in a London nursing home, the wife of Dr. Basil Rothery, of a son.

MARRIAGES

NEALE—WRIGHT.—On Dec. 24th, very quietly, at St. Pancras Parish Church, Arthur James Reginald Neale, of Croydon, to Caroline Isobel Wright, M.D., of London.

SANDERSON—DE LA HEY.—On Dec. 21st, at Folkestone, Geoffrey Hugh Sanderson, M.A., M.B., of Horncastle, Lincs, to Noreen Elizabeth, daughter of W. H. P. de la Hey, Courteen Hall, Simla, India.

DEATHS

COVEY.—On Dec. 26th, Edward Alan Rustat Covey, L.R.C.P., L.R.C.S., L.S.A., of Linden-grove, Shirley-road, Southampton, aged 65.

HADWEN.—On Dec. 27th, at Brunswick House, Gloucester, Walter Robert Hadwen, J.P., M.D., M.R.C.S., L.R.C.P.

KEEN.—On Christmas Day, 1932, Dr. Agnes Keen, of London-road, Bromley.

ROSE.—On Dec. 25th, at "Grey Walls," Seaford, Capt. Frederick George Rose, M.A., Ph.D., R.A.M.C., late H.M. Consul, Stuttgart, aged 65 years.

SHEPHEARD.—On Dec. 31st, 1932, Philip C. Shepheard, J.P., M.R.C.S., L.S.A., of Abbots Hall, Aylsham, Norfolk, aged 94. R.I.P.

WILSON.—On Dec. 27th, at St. Thomas's Hospital, London, William Craig Wilson, B.A., M.B., Ch.B., of Cleveland-gardens, W., aged 27.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

OBITUARY

SIR ALEXANDER HENDRY, K.C.V.O., M.D. Edin.

FOR 22 years, ending last January, Sir Alexander Hendry was continuously associated with the Royal Household at Balmoral. He belonged to the neighbourhood, being born at Braemar in 1867, and was educated at Aberdeen grammar school before going on to the University of Edinburgh. Graduating in medicine in 1892, he was soon established in practice at Ballater, where he was to spend the rest of his life. He acted as certifying factory surgeon for the district, and was later medical officer for several parishes. In 1904 he began his medical attendance at Balmoral Castle, and six years later he was appointed surgeon apothecary to the Household there. He became a Member of the Victorian Order in 1911, and a Companion in 1924; promotion to knighthood followed in 1931. He was a justice of the peace for Aberdeenshire, and was elected provost of Ballater last year. He died on Dec. 29th at Aberdeen.

Sir Alexander Hendry married twice. His second wife, who survives him, is the daughter of the late Mr. George White, of Great Missenden.

WALTER ROBERT HADWEN, M.D. St. And.

Dr. Hadwen who died on Dec. 27th at his home at Gloucester, after being taken ill with heart trouble on Nov. 29th, had long been president of the British Union for the Abolition of Vivisection, and for many years laboured in the public advocacy of the repeal of the Vaccination Acts and the abolition of vivisection; but though opposed to scientific medicine he supported movements connected with temperance, food, hygiene, sanitation, education, and burial laws. He was a magistrate, and did much municipal work in Gloucester. Born at Woolwich in 1854, he was the eldest son of Mr. W. R. Hadwen, of Burnham, Somerset. He was educated at a private school and Bristol University College, and 15 years later took up medicine when he entered the Bristol medical school, and qualified M.R.C.S., L.S.A., in 1893. Although so late in the field, he became a prizeman and gold medallist in surgery at the Bristol Royal Infirmary, after having taken prizes in physiology, operative surgery, pathology, and forensic medicine. He obtained the M.D. St. Andrews in 1897. He travelled widely, and his published works cover a range of subjects outside the practice of medicine. His name was prominently before the public in 1924, when he was acquitted at Gloucester Assizes on a charge of manslaughter, based on his treatment of a 10-year-old girl, alleged to have been suffering from diphtheria. The trial gave opportunity for him to assert disbelief in the germ theory of disease.

THE LEBANON HOSPITAL.—This mental hospital, which is situated on the road from Beyrout to Damascus, has this year treated 373 patients. The hospital comprises nine houses, with workshops, hall, laundry, and other buildings. Sixty beds have been added during the last two years, through legacies and special donations, bringing the total number up to 252. Every house that is opened brings a new stream of applicants for admission, so that, as fast as buildings can be provided, they are filled. The hospital is now in urgent need of two further houses (40 beds each), one for men and one for women. New houses, once built, are now almost self-supporting by the fees of the richer patients and the capitation fees paid by the Lebanese Government for the very poor. It is impossible, however, to obtain money locally for capita expenditure.

Medical Diary

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.
Tuesday, Jan. 10th.—5 P.M., Therapeutics and Pharmacology: Medicine: Special discussion on the Treatment of the Anæmias. Openers: Dr. L. J. Witts and Prof. Stanley Davidson.
Wednesday.— [illegible] tion of Proctology. [illegible] ig. Films; Sir Charles [illegible] Anastomosis of Colon. [illegible] : Operation for Fistula. Cases and specimens: Sir Charles Gordon-Watson: 1. Megacolon Resected. Mr. J. P. Lockhart-Mummery: 2. Epithelioma of Anus Treated with Radium. 3 and 4. Imperforate Anus. 5. Congenital Deformity of the Anus. 6. Lipoma of the Colon. Mr. W. B. Gabriel and Mr. Frederick Roques: 7. Carcinoma of Rectum Invading the Vagina and Uterus, and Treated by Perineal Excision and Vaginal Hysterectomy. Mr. Vaughan Hudson: 8. Villous Papilloma of Transverse Colon.
Thursday.—8 P.M., Tropical Diseases and Parasitology. Paper: Prof. C. D. de Langen (Batavia): Studies on Blood Regeneration and Blood Diseases in Java. Medicine: Pathology. Members of the Sections of Medicine and Pathology are specially invited to attend.
Friday.—8 P.M., Ophthalmology. (Cases at 8 P.M.) Mr. Tudor Thomas: Corneal Transplantation of an Opaque Cornea (with demonstration of the case).

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.
Monday, Jan. 9th.—8 P.M., Pathological Evening.

HARVEIAN SOCIETY OF LONDON.
Thursday, Jan. 12th.—8.30 P.M. (at 11, Chandos-street, W.), Annual General Meeting. Mr. C. P. G. Wakeley: The Rôle of Specialisation (Presidential address).

SOUTH-WEST LONDON MEDICAL SOCIETY, Bolingbroke Hospital, Bolingbroke-grove, Wandsworth Common.
Wednesday, Jan. 11th.—9 P.M., Mr. F. N. Doubleday: Dental Infection as a Source of General Disease.

WEST LONDON MEDICO- [illegible]
Friday, Jan. 13th.—7.15 [illegible] Brompton-road), Di [illegible] discussion, at 8.30 [illegible] Mr. Timbrell Fisher.

PADDINGTON MEDICAL SOCIETY.
Tuesday, Jan. 10th.—9 P.M. (at the Great Western Royal Hotel, Paddington), Dr. T. Drummond Shiels: The Objects and Methods of the British Social Hygiene Council. Visitors are invited.

PHARMACEUTICAL SOCIETY OF GREAT BRITAIN, 17, Bloomsbury-square, W.C.
Tuesday, Jan. 10th.—8.30 P.M., Dr. G. Roche Lynch: Poisons and their Effects.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.
Monday, Jan. 9th, to Saturday, Jan. 14th.—Lambeth Hospital, Brook-street, S.E. Frid., Demonstration of selected cases of general medical and surgical interest at 2 P.M.—Open only to Members and Associates of the Fellowship of Medicine.

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith-road, W.
Monday, Jan. 9th.—10 A.M., Medical Wards, Skin Dept., Genito-urinary Operations. 2 P.M., Medical, Surgical, Eye, and Gynæcological Out-patients, Surgical Wards, Operations.
Tuesday.—10 A.M., Medical Wards, Surgical Demonstration. 2 P.M., Medical, Surgical, Throat, Nose, and Ear Out-patients, Operations. 4.15 P.M., Lecture, Mr. Tyrrell Gray: The Rôle of the Mesentery.
Wednesday.—10 A.M., Medical Wards, Children's Out-patients. 2 P.M., Medical, Surgical, and Eye Out-patients.
Thursday.—10 A.M. [illegible] Fracture Demonstration. [illegible] Eye, and Genito-urinary [illegible] Lecture, Dr. Scott Pinch [illegible]
Friday.—10 A.M., S [illegible], Lecture: Therapeutics. 2 P.M., Medical, Surgical, and Throat Out-patients. Operations.
Saturday.—10 A.M., Throat Operations, Medical and Surgical Wards. Surgical and Children's Out-patients. The lectures at 4.15 P.M. are open to all Medical Practitioners without fee.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.
Tuesday, Jan. 10th.—5 P.M., Sir E. Graham-Little: Cicatricial Alopecia.
Thursday.—5 P.M., Dr. W. J. O'Donovan: Stocking Erythroderma.

CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn-road, W.C.
Friday, Jan. 13th.—4 P.M., Mr. C. Gill-Carey: Rhinological Aspects of Asthma.

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, Denmark-hill, S.E.
Thursday, Jan. 12th.—9 P.M., Mr. H. Edwards: The Treatment of Minor Injuries.

GREAT NORTHERN HOSPITAL, Holloway-road, N.
Tuesday, Jan. 10th.—3.15 P.M., Dr. C. C. Beatty: Demonstration of Cases.

ST. MARK'S HOSPITAL, City-road, E.C.
Thursday, Jan. 12th.—4 P.M., Mr. L. E. C. Norbury: Colostomy.

GLASGOW POST-GRADUATE LECTURES.
Wednesday, Jan. 11th.—4.15 P.M. (at the Western Infirmary), Prof. T. K. Monro: Medical Cases.

Appointments

City of London Maternity Hospital, City-road, E.C. Christie-Brown, R., M.S. Durh., F.R.C.S., Obstetric Surgeon; Dodds, R. L., M.B. Belf., F.R.C.S. Eng., O'Sullivan, J. V., M.D. N.U.I., F.R.C.S. Eng., and Blaikley, J. B., M.B. Lond., F.R.C.S. Eng., Asst. Obstetric Surgeons; Connell, J. G., M.R.C.S., Asst. Resident M.O.

Vacancies

For further information refer to the advertisement columns

Bolingbroke Hospital, Wandsworth Common, S.W.—H.P. At rate of £120.
Bolton Royal Infirmary.—H.P. £200.
Bury Infirmary, Lancs.—Sen. H.S. At rate of £200.
Central London Ophthalmic Hospital, Judd-street, W.C.—Sen. and Jun. H.S. £120 and £100 respectively.
Central London Throat, Nose, and Ear Hospital, Gray's Inn-road, W.C.—Hon. Second and Third Assts.
Dublin, Saint Michael's Hospital, Dun Laoghaire.—Ophth. S.
Enfield Urban District Council.—Two Asst. M.O.'s of Health. Each £300.
Evelina Hospital for Sick Children, Southwark, S.E.—Hon. Physician to Skin Dept. Also H.P. At rate of £120.
King Edward Memorial Hospital, Ealing.—Jun. Res. M.O. £150.
Leeds Hospital for Women.—H.S. At rate of £100.
Leicester [illegible] Surg.
London [illegible] *Great Ormond-street, W.C.*—Res. [illegible]
London Jewish Hospital, Stepney Green, E.—Second Radiologist.
Manchester, St. Mary's Hospitals.—Asst. M.O. for Children's Out-patient Dept. At rate of £150. Res. Obstet. O. for Whitworth-street West Hospital. £175. Also Three H.S.'s to Special Depts. Each at rate of £50.
Margate and District General Hospital.—Res. M.O. £150.
Market Drayton, Cheshire Joint Sanatorium.—H.P. £250.
Middlesex County Council.—Ophth. S. £2 12*s.* 6*d.* per session.
Middlesex Hospital and Medical School, W.—Medical Registrarship. £300.
Newcastle General Hospital.—Two H.S.'s and One H.P. Each at rate of £150.
Northwood, Mount Vernon Hospital.—Gynæcologist.
Nottingham City Mental Hospital.—Jun. Asst. M.O. £350.
Rotherham Hospital.—H.P. £180.
Royal Chest Hospital, City-road, E.C.—Physician for Out-patients' Dept.
Royal London Ophthalmic Hospital, City-road, E.C.—Gifford Edmonds Prize in Ophthalmology. £100.
Royal Northern Hospital, Holloway, N.—H.P. At rate of £70.
St. Albans, Herts, Cell Barnes Colony for Mental Defectives.—Deputy Med. Supt. £600.
St. Giles' Hospital, Brunswick-square, Camberwell, S.E.—Res. Med. Supt. £1300.
St. John's Hospital, Lewisham, S.E.—Hon. Skin Physician. Also Res. H.P. and Cas. O. Each at rate of £100.
St. Stephen's Hospital, Fulham-road, S.W.—Clin. Asst. At rate of £100.
Society for Prevention of Premature Burial.—Medical Examiners.
Southampton Children's Hospital and Dispensary for Women.—Res. M.O. At rate of £150.
South London Hospital for Women, Clapham Common, S.W.—Surg. Reg. 50 gns. Out-patient M.O. and H.S. Each at rate of £100.
Tilbury Hospital, Essex.—H.S. £140.
University College Hospital, Gower-street, W.C.—Hon. Asst. Surg. to Ear, Nose and Throat Dept.
Victoria Hospital for Children, Tite-street, Chelsea, S.W.—Hon. Surg. Reg., H.P., and H.S. Each at rate of £100. Also Out-patient Anæsthetist. 10*s.* 6*d.* per attendance.
West End Hospital for Nervous Diseases, Gloucester-gate, N.W.—Sen. and Jun. H.P.'s. At rate of £150 and £100 respectively.
West London Hospital, Hammersmith, W.—Cas. O. At rate of £250. Also Asst. Gynæcologist.
Western Ophthalmic Hospital, Marylebone-road, N.W.—Hon. Anæsthetist. One guinea a visit.

The Chief Inspector of Factories announces a vacant appointment for a Certifying Factory Surgeon at Newport, Isle of Wight.

NOTES, COMMENTS, AND ABSTRACTS

THE MEDICAL SCHOOLS AND THE NATION'S HEALTH[*]

BY JAMES YOUNG, D.S.O., M.D., F.R.C.S. EDIN., F.C.O.G.

GYNÆCOLOGIST TO THE ROYAL INFIRMARY, AND PHYSICIAN TO THE ROYAL MATERNITY HOSPITAL EDINBURGH

[Dr. Young began by pointing out that the due relation of medical schools and the medical profession to recent developments in public health can be understood only if we keep prominently before our minds the sources from which these have sprung, and the factors responsible for the rapidity of their growth within the past few generations. He then described the great hygienic movements of the nineteenth century, as the community awoke to the squalor and filth which accompanied the rising industrial age. A reduction of the death-rate and a prolongation of average individual life became associated with the efficient disposal of sewage and the provision of a pure food- and water-supply. But he found these things to owe little to the medical schools, though medicine played its part in the advance, particularly by discovering the bacterial nature of infectious disease. Modern sanitation, as the dominating achievement of the nineteenth century, he considered due in the main to the vision and energy of public men and corporations, and not to organised medicine. He asked his hearers to reflect upon the fate of communities to-day if the defences of hygiene were withdrawn, when all pestilences would be rapidly disseminated by modern methods of intercommunication; but inevitable though it was that the medical profession and the public should be pervaded with the spirit of prevention, he found the organisation and traditions of the medical schools not to promote that spirit. He continued :—]

The Emphasis upon the Curative Aspects

It is a matter of commonplace that the emphasis in medical teaching is placed upon the curative aspects, that is, the training is so organised as to prepare the doctor for the recognition and treatment of frank disease. His preliminary years are spent in the study of the *medical sciences* to provide him with that framework and that scientific attitude necessary for his later approach to the clinical subjects embraced within the *medical art*. The function of the medical art, as we understand it, is the alleviation or the cure of disease, and so dominating has this therapeutic aspect become by the necessities of tradition and evolution that it is difficult to see how such a conception as the elimination of disease by the protection of health can find for itself a place in such unfamiliar surroundings. And we must make no mistake in regard to the magnitude of its claims; it demands priority of position and broad space for its growth and expansion.

Where, in our schools organised for the study of disease, can we find a place for the gospel of health? Where, in a scheme leading from chemistry and anatomy and physiology through pathology and the post-mortem room to clinical medicine and clinical surgery, can we break the chain to accommodate the new evangel? It would be hard to expect the professors of medicine and surgery to adjust themselves to the rôle of hygienists, for are they not the completed product of the schools of disease, and have they not reached their academic distinction and power just because they are proved exponents of its teaching, or have discovered, perchance, newer methods for the diagnosis and treatment of disease? And, if we thrust upon their shoulders, already heavily burdened with the load of disease, the added task of hygiene, as some with more enthusiasm than a sense of fitness have urged, where will we have them begin, and how will they proceed?

Modern Specialism and the Narrow Outlook

In this connexion we have only to reflect a moment to recognise how increasingly pledged medical thought and tendency have become within recent years to a preoccupation with disease. For have we not, during the past few generations, unleashed a whole new host of ardent seekers in the field of the morbid? The growth of specialism, both in its rapidity and its extent, has become one of the most remarkable features of modern medicine. We may with justice describe the present era as that in which almost every organ and function in the body has evolved its own specialism and its own particular votary.

The general results of such a remarkable development must naturally be profound. To it we must in part look for an explanation of our present hospital impasse, because each such specialism has surrounded itself with an elaborate and expensive system of equipment, personnel, and remedial measures, and has flourished only because it has found a home within the walls of the wealthy organisation of our charity hospital, to which the greater part of the community has had perforce to turn in its time of need.

A further result of great significance is that the claims of the specialty in regard to the rapidity of its expansion, its technique, its literature, &c., are so insistent that it may, and often does, imply that the specialist must from his earliest days forsake the broad territory of medicine and devote himself entirely to the restricted field of his chosen craft. Once the die is cast it is inevitable that the more his life is occupied with his specialism the more does he lose touch with the general aspects of the medical art. A general practitioner friend of mine of wide experience and sound discrimination has aptly expressed the position by the remark that "the specialist is usually a bad doctor," and it is not difficult to see that in such an impeachment there must be a sound basis of truth. The circumstances of the specialist's life are prone towards a still further narrowing of outlook in that from the nature of his calling he is so frequently summoned to the patient only when the ailment is advanced and even terminal. This is probably specially true of the surgical specialties though it applies in considerable measure to those more purely medical. It thus happens that the preoccupation of specialism is apt to be largely with a cruder diagnosis and even more with a cruder treatment and to find small opportunity for the cultivation of that philosophic spirit that derives its chief exercise and its greatest satisfaction in the study of ultimate causes and in prevention.

It is in the nature of specialisation that it cannot easily escape from the limitations that it creates for itself. The danger is that in our admiration for the precision of its knowledge or the manipulative skill of its exponents we should forget the relative and topical character of its contribution. For the study of a separate organ receives its complete sanction only when it is related to the whole, and by the whole we mean the organism in respect, not only of its anatomy and its physiology, but also of its environment and its habits, its sociology, and those other agencies which by their interplay react on the health and well-being of the individual.

---

[*] Abridged from the presidential address to the Edinburgh Obstetrical Society, delivered on Nov. 9th, 1932.

The outstanding triumphs of modern surgery have surrounded it with a glamour that has tended to exalt it above its proper sphere in the medical organon and to give to its votaries a place and power which is hardly commensurate with the degree in which their craft has contributed to an enrichment of the science and art of medicine in the wider and fuller sense. More significant, however, than such questions of pride of place, the movement thus symbolised has tended to a corresponding depreciation of the value of general medicine and of the paramount importance of the general outlook. It has succeeded in establishing the specialisms in a place of primary authority when their function should be contributory and ancillary. At the best the function of specialism is that of the expert witness, at its worst it may degenerate unless controlled into a cruel and merciless exploitation of the public. It may inspire the carrying out of surgical operations that, based upon a limited diagnosis, are condemned to failure and it may lead to the extirpation of diseased organs by surgeons who pursue their routine work unmindful of the factors which in the community may be breeding *in perpetuo* material for their scalpel.

The supreme task of the next generation, alike in the interest of health ideals as of curative medicine, is a readjustment of our outlook in these matters. It is the opinion of many who have been disquieted by present medical tendency that the salvation of our art in its great duality of function is to be found in one way only—namely, by the creation of a body of well-trained practitioners to whom will be handed back the authority often usurped by those who are ill-equipped to exert it with judgment and skill. There can be no question that only in so far as we recover for the mind at the centre the supreme decisions in regard to health and disease will we lead to a reintegration of much that is disruptive in modern medicine and only in this way will we recapture for the profession its soul and, for the public, its safety.

[Dr. Young here dwelt on the great effort of James Mackenzie to assess the extent to which disease is really capable of diagnosis, and continued :—]

Failure of Medical Schools

There is no more eloquent sign of the inability of the medical schools as at present organised to exercise creative leadership in these matters or even to accommodate the ideals of preventive hygiene than the nature of the reception which some of the new health movements have received at their hands. Take, for example, those national aspirations for the protection of child life and child welfare, aspirations that owe their genesis in the main to a social conscience stirred by the amount of ill-health revealed in school-children when, consequent upon the enactment of compulsion in education, they first came under the organised supervision of the community. This movement had grown to be national and it had become an important charge on municipal health activities before it had created a ripple on the surface of organised medical opinion. It was only as recently as 1923 that out of deference to this strong social conviction the General Medical Council added the subject of infant hygiene to its recommendations for the revised medical curriculum. Despite the pressure reaching them from such different and such influential sources and the great opportunity presented to them of identifying themselves with the most important of all health movements, that directed towards the young child, the medical schools even now make for the most part only a very inadequate provision for the teaching of their students in matters of infant health. It has been left to the public authorities through their child welfare clinics and such independent bodies as the Mothercraft Training Society to explore the great new field presented by the healthy child and to garner for themselves the knowledge required for the expansion of such communal efforts. It is unfortunate that in regard to this beneficent social awakening to the value of child life and health the organised medical profession has lost a great chance of leadership.

As a further instance of restricted vision and the difficulty of our medical schools to align themselves with health-saving activities, let us take that world-wide movement for the protection of motherhood. It has long been evident that one essential step towards an alleviation of the dangers of childbirth is *an improvement in the teaching of our medical* students in midwifery. In the past this has been carried out by the schools in a manner sometimes described as scandalous. Despite the gravity of the issues involved, despite the widespread social disquietude provoked by the spectacle of so many young and healthy women annually lost or hurt in the performance of a physiological act, relatively few schools have yet found it possible to make provision for the bare teaching requirements.

The chief reason advanced for the delay in providing adequate teaching in midwifery and child health is the already crowded character of the medical curriculum and the lack of time available even for such an urgent need. There is, of course, considerable truth in an objection based upon the multiplication of the specialisms that have demanded inclusion in the teaching programme. At the same time there is reason for the view that, apart from such considerations, the curriculum has acquired a rigidity that has deprived it of the capacity of responding to the needs of each new age. It is, for example, often pointed out that botany, which owed its original inclusion to the fact that so many of the drugs used in medicine were derived from the vegetable kingdom, can no longer justify its retention on such grounds. It is the opinion of many, also, that anatomy has a quite inordinate amount of time allotted to it and that the full purpose of the admittedly important part this science must always retain would be served were a shorter period appropriated for its study. There can be little doubt that the overwhelming place sometimes claimed for anatomy has its origin in the position this subject has occupied in the historical development of the medical art. It was, in a sense, the first and, for long, the only medical science. We are apt to forget that the time has long passed when its association with anatomy gave to medicine its only claim to science, when, indeed, the medical art was compounded of anatomy and obscurantism.

It is thus arguable that the difficulties facing the medical schools in the way of making room for new subjects as these arise in the evolution of our craft spring, at least in part, from that same lack of resilience to the impact of new ideas to which we have been directing attention in the preceding pages. As a further example of this same irresponsiveness to big preventive ideals, let us take the attitude of the schools to the subject of nutrition, that most pervasive of all the factors of health. Where, in our schools, do we find this expounded with the completeness and thoroughness which it demands? Can we conceive of any subject which is more suited for earnest study by our great schools or one which offers to them such an opportunity for creative leadership and instruction? The extent of the influence wielded by nutrition in the mental and physical welfare of the community it is impossible to overrate. In a manner the very essence of health is sound nutrition and of disease faulty nutrition. From the antenatal period onwards through infancy and childhood this influence is supreme and the ultimate individual in his reactions and his resistance to his environment, including the extrinsic factors of disease, is, in a real sense, a product of his nutrition.

Who can say how many of the diseases of our present civilisation spring from the food we eat? Enough has already been learnt to suggest that the dental caries so typical of our race springs predominantly from the vitiation of the processes of teeth formation in the unborn fœtus or in infancy as a sequel of dietetic deficiency. Rickets is a disease of deficiency. Tuberculosis is in great part a disease spread by our infected milk-supplies. Dyspepsia, infection of the tonsils, rheumatism, heart and kidney disease, and a host of other morbid states that can be mentioned, who is to say how many of these are essentially the products of faulty nutrition? And of the "undiagnosable" diseases of Mackenzie, comprising some 60 per cent. of all diseases according to this eminent medical philosopher, in how many is the key to their secrets to be found, not in the abstruse biochemical or immunological investigations that engage the energies and the intellects of our laboratories, but in the far-reaching influences of racial nutrition?

It is true that during the past generation much research of outstanding value on nutrition has emerged from medical laboratories. The work of Hopkins, Mellanby, and others has opened up a new epoch in the study of the subject. Nevertheless, the scientific progress which such investigations connote has been the product of isolated laboratories and the work of isolated individuals rather than the outcome of an organised effort springing from an appreciation by the schools of the great significance of the question. Doctors set out on their public career largely ignorant of its far-reaching importance, and how could it be otherwise when to their teachers, committed by the nature of their calling to an overwhelming concern with disease, the chief interest of nutrition arises from the manner in which it contributes to the production of such conditions as obesity, diabetes, and so on? The part played by nutrition in the determination of the health and growth of the individual from the intra-uterine period onwards throughout life, its influence on the industrial and social welfare of the race, the extent of the known and the fascinating fields of the unknown still waiting to be explored, to these and kindred subjects the student's mind had never been directed because there had been no teacher to whom this great opportunity had been presented and on whom this great responsibility had fallen.

(*To be concluded*)

INSTRUCTION ON SEX QUESTIONS

THE bulky but original writings upon the sexual question of Havelock Ellis, Hirschfeld, Westermarck, the various schools of psycho-analysis, K. B. Davis, R. L. Dickinson, and others, continue to be popularised in small volumes by writers of varying degrees of competence and erudition. Some of the books which reach us are written for children; others for adolescents, for brides and bridegrooms, for religious persons, and for the nondescript general public.

As is pointed out in a preface by Mr. Norman Haire, editor of the Library of Psychology and Sexology Series, Dr. Evans is an American who, writing for an American public, mixes science, religion, and sentiment in his book.[1] This is a somewhat rhetorical exposition of the part which should be played by the husband in his sexual approaches to his wife. The author's chief aim would appear to be to interpret to a well-meaning but stupid man the timidities and inhibitions which characterise the average woman's attitude to sex, and which, unless taken into account by her husband, will spoil her married life. The author hopes these fears will be dissipated if the young wife will sit down by her husband and read the pages of his book which begins with a description of the nervousness of the young bride on the first night of her marriage, and ends with an account of the positions in which coitus may take place.

In explaining how a book entitled "How I Was Born"[2] (which is intended for adults and not, as the title might suggest, for children) came to be written, Dr. Bryan makes an astonishing statement. He says that at the annual conference of the British Medical Association held at Eastbourne in 1931, a demand was made not only by doctors, but by eminent churchmen and by other well-known people, that the mysteries of sex should be cleared up in a plain and wholesome exposition by a medical man. After a year had passed, writes Dr. Bryan, no volume of reasoned explanation of these so-called mysteries had been placed before the public, and his book was written to fill the gap. The unawareness which the author reveals of the torrent of such "wholesome expositions" which has been let loose upon the public since the war, is matched by the apparent ignorance displayed in several of the 22 chapters of the book of the literature of the subjects therein expounded. Moreover, the reader is informed in a preface that the book is "not written with profound gravity but with a light touch which, while it may bring a frown to the few, will make it more readable to the many." While saying little about the psychological aspects of sex or marriage, it contains chapters full of anecdotes on castration, hybrids, hermaphrodites, and virginity. It is difficult to see to what class of reader this book will prove useful, unless to those in search of after-dinner stories.

A third book,[3] by Dr. Douglas White, aims at introducing the reader to "a fresh outlook on sexual questions which has mostly developed since the beginning of the century." It is, in fact, a praiseworthy attempt by a medical man with religious leanings to enunciate a philosophy of the sexual life in terms of modernist Christianity; or, in the author's words, to suggest "such an outlook on sex morality as may make an appeal both to the rational, ethical, and spiritual nature of those who desire to think and act in accordance with the highest ideals of human life." This book will probably meet the requirements visualised by the ecclesiastics who addressed the British Medical Association at Eastbourne, better than would the preceding one.

Dr. Wright states that her book[4] has the object of building up in young people "an attitude of mind towards sex which will view the whole question against the background of evolution in plant and animal life." This purpose is well fulfilled. The volume is abundantly illustrated, and is simply divided into four chapters entitled: sex in plants;

sex in animals; sex organs and their growth in human beings; and psychological development of sex instinct and its control. The last chapter raises some delicate questions about which there is as yet no formulated medical opinion, among them that of masturbation. The author's distinction between "harmless masturbation" which disappears of itself, and harmful masturbation which may produce physical disease of the sex organs, will not be accepted by those medical psychologists who hold that the injuriousness of the practice depends on psychological rather than on physical factors. Nevertheless, Dr. Wright's book could safely be given by parents to their sons or daughters when these reach adolescence.

APPLYING KNOWLEDGE TO INCREASE HAPPINESS

THE VALUE OF "AWARENESS"

SOME remarks made by the Regius professor of physic at Cambridge at a reception held last month at Institute of Medical Psychology, and briefly abstracted in our columns at the time,[1] contain a timely message for the New Year. "It has been said that the French rationalism of the eighteenth century cleared the ground for the upbuilding of natural science in the nineteenth. We can therefore understand," said Prof. Langdon Brown, "why nineteenth century science was inevitably materialistic. But that century also saw the romantic revival. There were consequently two diametrically opposed tendencies which had to be reconciled somehow. It was achieved by a hard core of materialism covered over by a veneer of romanticism. Changing the metaphor, the nineteenth century made for its goal with the aid of blinkers. But however much blinkers assist in concentrating attention on the goal, they prevent the wearer from seeing what is overtaking him. This may be a help to a horse, but it is a disadvantage to a man. The nineteenth century had no conception of what was overtaking it.

"The note of the twentieth century on the other hand is 'awareness.' It is much more aware of and sensitive to its environment. At present, however, it is only half aware. The blinkers are down, but no real adjustment has as yet been made. Hence there is great unhappiness. The old values have been swept away, without satisfactory new ones to take their place. If I didn't feel that a more complete awareness would help to remedy this, I should despair that we should be able to achieve anything at this institute. But I do most emphatically believe that we can do much by helping sufferers to understand more of the way in which their minds and emotions work. I was recently reading Sir Arthur Keith's description of his amazement when he found that his account of evolution was met by the mental attitude of Dayton, Tennessee. We have to remember that in matters of psychotherapy most of the patients that come here have the mental attitude of Tennessee, and we have to start from that point. I do not practise formal psychotherapy," Prof. Langdon Brown went on, "but I have been driven by sheer force of experience to realise the need for a more psychological approach to medicine. I was brought up in a most materialistic age of medicine, and only slowly came to realise the inadequacy of such an attitude. I found that quite as many people were ill because they were unhappy, as were unhappy because they were ill. So anxious were the former group to avoid that favourite diagnosis of 'just nerves' that they produced physical symptoms to account for their distress; yet the symptoms were not consistent with any organic disease, though they were often consistent with a disturbance of the sympathetic—i.e., the emotional, nervous system.

"To the patient who said 'I should be so ashamed if it is just nerves,' my usual reply was something along these lines. When I first went into the dissecting room, still under the impression that 'just nerves' meant just an imaginary illness, I saw a dissection of the brachial plexus. I thought that if a man's heart or lungs could go wrong, there was no reason why a complicated network like this plexus should not go wrong also. Then I go on to explain that this is not an exact illustration—for it is not a disturbance of these large nerve trunks which produces the symptoms he complains of, but the tiny branches between one nerve-cell and its neighbour. These particularly belong *to the association cells, and the point which* distinguishes the human brain from that of the lower animals is its wealth of such association cells. Why then, I ask, should you be so ashamed of something going wrong in what is so essentially a human characteristic?

In this way I can often pave the way for their being more receptive of psychotherapy. The illnesses dealt with at this institute are not imaginary, though they are connected with the image-making part of the brain. They often depend on the reactions between themselves and their nearest who ought to be, but are often not, their dearest. These emotional reactions are often painful, because they are only half-aware ones, and the unfavourable environment prevents satisfactory adjustments from being made. I often used to think, looking at the packed rows of patients in the out-patient room, that a lot of the good they undoubtedly receive from going to hospital was the opportunity it gave them of unburdening themselves to their neighbours, though they attributed it more to the bottle of medicine they were given.

"This institute," Prof. Langdon Brown concluded, "aims at scientific use of this unburdening and at skilled explanation of the symptoms resulting from these disagreeable and painful reactions arising from uncomprehended sources. It provides not only for proper treatment of nervous symptoms, but ensures that organic disease as a possible cause for such symptoms should not be overlooked. The work done here is unique, and marks a change in the whole point of view of medicine. It could thus assist in alleviating much misery and unhappiness so prevalent to-day."

DRIED MILK WITH ADDED IRON

THE firm of Ambrosia Ltd., Brighton Chambers, Denman-street, London, S.E.1, produces Ambrosia, a full cream Devonshire dried milk, the process of preparation not, it is stated, impairing the vitamins in fresh liquid milk. The firm have now placed on the market a combination of Ambrosia with iron ammonium citrate, designed for the treatment of anæmia in infants, nursing mothers, and other subjects where this form of nutrition is indicated. The preparation, to which, if necessary, extra vitamin D can be added, meets the recommendations in regard to the nutrition of infants contained in the recent circular letter from the Ministry of Health through its advisory commission on the subject.[1] The iron ammonium citrate added to the reconstituted Ambrosia products is to be prescribed for adults in the dose of grs. 10 per half pint, the suggested dose for infants being gr. 0·29 per ounce. The added vitamin D can be supplied in the preparation at an equivalent in antirachitic value to a teaspoonful of high grade cod-liver oil to one pint of milk. We are informed by the proprietors that they have received from various infant welfare centres evidence of the satisfactory employment of the preparation.

ENTERTAINMENT FOR THE BLIND.—From time to time we have referred to the excellent work which Dr. F. W. Alexander is doing for the blind. He has endeavoured to simplify the task of learning Braille; he has proposed a useful method of duplicating Braille broadsheets; and he has enlisted the aid of handicraft workers in making various kinds of puzzles (THE LANCET, 1931, i., 1006; 1932, ii., 224). He is now turning out quantities of literary puzzles in Braille—anagrams and the like—which will bring welcome employment to the leisure hours of blind people who can appreciate this type of entertainment. Those in touch with suitable recipients for such puzzles should apply to Dr. Alexander at Bankside, Ferry-road, Teddington, Middlesex.

ADDRESSES AND ORIGINAL ARTICLES

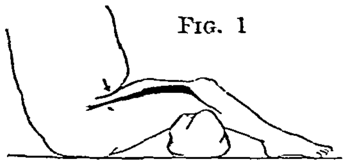
PHLEBITIS *

BY A. DICKSON WRIGHT, M.S. LOND., F.R.C.S. ENG.
SUPERNUMERARY ASSISTANT SURGEON, ST. MARY'S HOSPITAL, LONDON

PHLEBITIS is almost entirely a disease of the lower extremities, where the veins are subjected to higher pressures and stagnation of the venous blood occurs from the effect of gravity. In varicose veins, the stagnation and pressure are more marked and phlebitis consequently more frequent.

Rest in bed increases the stagnation in the veins of the leg, because of the cessation, to a great extent, of the muscular contractions, which are so important an aid to the venous flow. Frequently, as in pneumonia, the sitting position maintained for a considerable period of time naturally increases the pressure in the veins of the legs. If, in addition, the patient is obese or pregnant an abdominal "dewlap" hangs down and presses upon the femoral veins in Scarpa's triangle (Fig. 1). In the dorsal recumbent position, the venous flow is also interfered with by the pressure in the gluteal region, causing the muscles to be squeezed into the pelvic foramina, and thus obstruct the gluteal veins. It can be realised how an air ring would be more liable to cause venous stagnation in this way (Fig. 2). The femoral vein in the front of the leg is safe from pressure, but not so with the posterior tibial pressed against the intermembrane by the calf muscles (Fig. 3). The osseous "donkey" pillow under the knee presses upon the popliteal veins and is definitely a harmful appliance (Fig. 4). Phlebitis of the lower part of the posterior tibial vein is common after operations, and I have often observed a connexion between tender indurations in the lower calf and post-operative lung infarcts.

FIG. 1



The abdomen enlarged by pregnancy, tumour, or obesity causes obstruction of the femoral vein in sitting position.

Many Possible Causes

Phlebitis is well known as a decubitus complication in certain conditions :—

(1) The *puerperium* probably provides the largest number of cases. It must be noted that the inflammation and thrombosis may occur in the deep veins, the normal superficial veins, or varicose veins, and may vary in its extent. The title of "milk leg" or phlegmasia alba dolens is often applied rather indiscriminately to all these conditions, a more precise diagnosis is essential both for treatment and prognosis.

(2) *The post-operative period.*—As in the puerperium, there is a greater tendency for the blood to clot intravenously because of the escape of clotting activating substance into the circulation, the result of trauma, and because of the 100–200 per cent. increase of blood-platelets as demonstrated by Howel Evans of Liverpool. The subjects of Cæsarean section and of splenectomy have to run a double risk.

(3) Fractures of the lower limb have to undergo prolonged immobilisation, and always result in considerable venous thrombosis.

(4) Medical cases provide a large quota and an analysis of 100 consecutive cases gave the following percentages: typhoid and paratyphoid 56 per cent., pneumonia 32 per cent., influenza 7 per cent., malaria 3 per cent., gout 1 per cent., and typhus 1 per cent.

In certain other conditions, phlebitis occurs as a complication without the patient being in bed :—

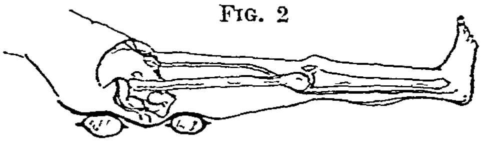
(1) *Pregnancy.*—I have seen a number of cases, mostly in varicose veins. I have recently encountered a case of fatal pulmonary embolism in the eighth month of pregnancy.

(2) *Trauma* to the leg or to a superficial vein frequently causes phlebitis.

(3) *Septic lesions* of the legs, especially insect bites.

(4) *Focal sepsis* in throat, mouth, or nose seems to be frequently connected with phlebitis, and should be looked for in every case which cannot be explained otherwise.

FIG. 2



Indicates how the pressure of an air ring is liable to cause pooling of venous blood.

(5) *Malignant disease* of the stomach.—The association of phlebitis in digestive disturbance is known as Trousseau's sign of malignant disease of the stomach. The tragic story of how Trousseau discovered his own fatal complaint by this sign is well known.

(6) *Thrombo-angiitis obliterans.*—Half the sufferers from this condition develop a painful *superficial* phlebitis of the leg at some time or other, and in many cases it is the first sign of the disease.

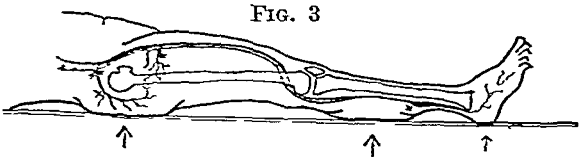
(7) *Thrombo-phlebitis migrans*, a chronic disease associated with phlebitis, occurring at intervals in all parts of the body. There is considerable pyrexia, and a low arterial blood pressure is a frequent association.

After the exhaustion of all possible causes, there still remain a large number of unexplained cases of phlebitis, the majority of which occur in varicose veins, and phlebitis must be looked upon as one of the commonest complications of varicosity.

Prophylaxis

Prophylaxis applies mostly to those cases occurring while the patient is in bed. The patient must not be kept too long in one position, if possible. The sitting position seems to be especially dangerous. Sleeping on the side at night in post-operative and puerperal cases should be allowed. The air ring should be avoided as far as possible, and the knee-donkey abolished entirely. Deep breathing and other exercises should be encouraged as suggested by Eugene Pool and L. R. Braithwaite. Waltman Walters, at the Mayo Clinic, recommends a high caloric diet and enough thyroid extract to produce temporary hyperthyroidism after operations. The trauma of the tourniquet seems to produce some cases, and the use of the pneumatic tourniquet will prevent these. The precaution of bandaging the legs firmly with Elastoplast bandages is of great value in patients who, having varicose veins, have to undergo an abdominal or other operation. The veins are kept obliterated by the pressure, and phlebitis in the varicose veins seems to be completely guarded against. Sometimes

FIG. 3



The pressure on the calf obstructs the posterior tibial vein.

---

* An address delivered at a post-graduate course at St. Mary's Hospital.

the veins can be dealt with by injection as a preliminary to any deliberate operation, which should be done a month after the treatment of the veins. The best arrangement for the sitting patient is shown in Fig. 5. The patient sits in a bed arm-chair. The arms prevent slipping and also take up about 20 *per cent.* of the patient's weight. The backs of the thighs are supported by a wedge-pillow which is kept from slipping by a prolongation, upon which the patient sits. The popliteal and posterior tibial veins are thus saved from pressure. The soles of the feet rest upon a sponge rubber pad on a foot-rest adjustable on the well-known trellis system used for telephones. A thoroughly comfortable patient is secured by this arrangement, and one much less likely to develop phlebitis from pressure upon veins.

FIG. 4

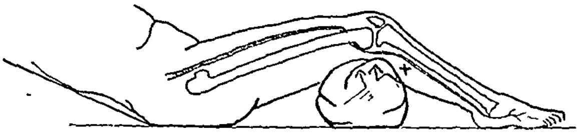


Diagram to show how the "donkey" pillow, under the knee, presses on the popliteal blood-vessels.

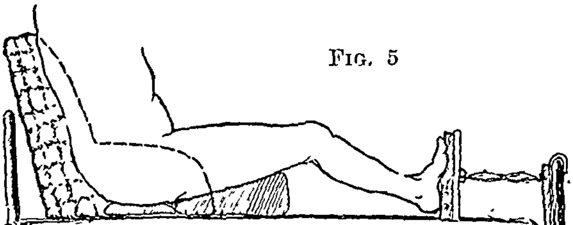
Treatment

Treatment of deep phlebitis.—When phlebitis is diagnosed in the posterior tibial vein, a firm elastoplast bandage to the knee will help to anchor the clot and prevent extension of the process up to the femoral vein. When the femoral vein is thrombosed, there is nothing to be done except to keep the patient horizontal, as the raising of the legs might predispose to embolism. Effortless action of the bowels is secured by paraffin purgatives and occasionally glycerin suppositories. The rubber bed-pan is used, with the patient lying down, and on no account must enemas or the sitting position for defæcation be allowed. After 14–21 days the swelling will start to subside, and the application of frequent bandages from foot to groin will hasten the return of the leg to normal proportions. When the swelling is all gone, the patient is allowed up with an elastoplast bandage on reaching well up the thigh. As the tendency to swell diminishes, the bandage is reduced in extent and finally ends below the knee. A change to Unna's stocking can be made later still, and finally an elastic bandage or stocking is worn. It is absolutely essential that all œdema should be controlled to lessen the weight of the leg and, more important, to help in the opening up of the collateral circulation. My experience with severe ulceration and eczema occurring from 7 to 25 years after femoral thrombosis convinces me that many of these cases must wear supports for ever. Future childbearing is best avoided after a white leg if possible, and in one case I recommended emptying of the uterus and sterilisation in a severe bilateral case the result of a previous pregnancy.

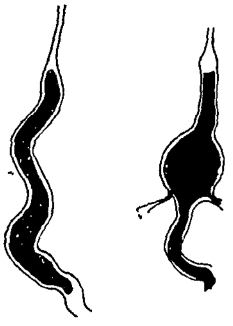
FIG. 5



The optimum position for the sitting patient.

Treatment of superficial phlebitis is a different problem because the clot can be prevented from travelling upwards by a rubber pad placed at its upper end (Fig. 7), and the inflamed vein firmly compressed by a tight elastoplast bandage below the pad. This tight bandaging seems a very painful process to the onlooker, but the rapid disappearance of the pain is most gratifying to the patient. The tight bandage expels the inflammatory exudates around and in the vein, compresses the clot and hastens its organisation. The patient is kept ambulant, even when there is a temperature, and this is generally gone in 48 hours by this method. When phlebitis occurs in varicose veins, keeping the patient up lessens the risk of embolism, because the current of blood is downwards in these veins. Moreover, the tortuosity and uneven calibre of the clots is a further safeguard against dislodgment (Fig. 6). Putting the patient to bed with an unsupported leg may lead to extension of thrombosis to the deep veins, with great risk of embolism. The bandage is kept on from two to six weeks, provided it stays in position and keeps tight. If, on its removal, some of the thrombosed veins are found to fluctuate, a stout needle should be inserted and the contents withdrawn and bandage reapplied. This hastens resolution and the contents can be examined bacteriologically, so as to make an early diagnosis should suppuration be developing.

FIG. 6



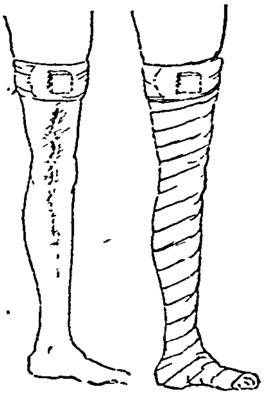
Shows how the irregular shape of the thrombi prevents dislodgment and also that the vein above the clot is of narrow calibre.

After six weeks of the bandage the venous indurations will be found to be practically gone and the attack of phlebitis a boon to the patient, in that the veins are obliterated and will not recanalise because of the pressure to which they have been subjected. I have treated many cases who have experienced in previous attacks the routine of six weeks in bed with belladonna or ichthyol locally, and I have not found one patient who preferred this latter method of treatment. There is no place for proximal ligation of veins in simple phlebitis of superficial veins as there is in suppurative phlebitis. I have found that the most certain way of producing phlebitis in a superficial vein of the leg is to ligature it. Proximal ligation only produces a fresh thrombosis, and if done close to the saphenous opening, the clot above the ligature may extend to the femoral vein.

I have been unable to comprehend the scientific basis of the elaborate ritual of spa treatment in the management of phlebitis, and cannot understand the value of the various glandular extracts and ferments in the treatment of a purely inflammatory disease. This compression treatment is also of the greatest value when an injection of sclerosing fluid produces an excessive reaction or the dreaded ascending phlebitis. It is also the best treatment when the *sloughing of the vein wall occurs or necrosis* of the tissues at the point of injection. If the leg is swathed tightly in an elastoplast bandage at the first sign of a necrosis and this is left on for a month or more the slough discharges itself, and the resulting ulcer epithelialises all unknown to the patient, who is thus saved much anxiety.

The condition of *periphlebitis* is often mistaken for true phlebitis. It occurs only in association with varicose veins and in the lower two-thirds of the leg. It is best described as a non-suppurative cellulitis of the perivenous tissues. It is a very painful condition. and the vein can generally be felt to be patent as it traverses the tender indurated affected area. The treatment is the same as for phlebitis except that the condition is no contra-indication to immediate injection of the varicose veins which should invariably be carried out. The condition of periphlebitis often leads to ulceration, the resulting ulcer being sometimes known as a "phlebitic" ulcer.

FIG. 7



Method of bandaging superficial phlebitis, with rubber pad and elastoplast bandage.

SCLEROSING INJECTIONS

The question of the injection treatment in patients who have suffered from phlebitis is a very vexed one. Firstly, in the case of obliteration of the femoral vein it is said that if you inject the varicose veins which develop many years after the disease you will rob the patient of the only veins that he has left. I have repeatedly found that this is not the case, and have come to the conclusion that these veins constitute an increased embarrassment to the venous return and their blocking by injection reduces instead of increasing the œdema, and helps to stave off the complications which arise from prolonged vascular imbalance in the legs.

Secondly, the occurrence of an attack of phlebitis in varicose veins is regarded by some as an absolute contra-indication to any sclerosing injections; others say that an interval of from one to five years must elapse before any injections are given. It is said that these cases are liable to fatal embolism and acute ascending phlebitis if injected. So it results that most of these patients are allowed to remain in possession of varicose veins which become the seat of constantly recurring attacks of phlebitis with all their attendant pain, anxiety, expense, and risk. I have in a large number of cases ignored the history of recent superficial phlebitis, dealing with the varicose veins by injection, and have had no case of embolism. I have had several cases of excessive inflammatory response from the injection, but this can be very satisfactorily controlled if treatment by firm strapping is instituted.

Summary

(1) Phlebitis is often a decubitus complication and can be, to a certain extent, prevented by attention to certain details. (2) Superficial phlebitis may be the first sign of three diseases: thrombo-angiitis obliterans, cancer of the stomach, and thrombo-phlebitis migrans. (3) Phlebitis is a common complication of varicose veins. (4) The treatment of phlebitis in deep and superficial veins is essentially different. In superficial veins, and especially in varicose veins, the risk of embolism and extension of the phlebitis is reduced by keeping the patient ambulant, and the resolution of the inflammation is hastened by compression. (5) Past femoral thrombosis is not a contra-indication to the injection of obvious varicose veins. (6) Varicose veins, the seat of repeated phlebitic attacks, should be dealt with by injection.

MASKED HYPERTHYROIDISM AS A CAUSE OF HEART DISEASE

BY JOHN R. H. TOWERS, M.D. CAMB.,
M.R.C.P. LOND.

MEDICAL REGISTRAR, ST. MARY'S HOSPITAL, LONDON; LATE RESIDENT MEDICAL OFFICER, NATIONAL HOSPITAL FOR DISEASES OF THE HEART

FOR many years it has been recognised that dysfunction of the thyroid gland may give rise to cardiac symptoms and these may be the only manifestation of that disorder. In recent years it has been appreciated that there exists a group of patients with cardiac disease, due to dysthyroidism, though they have not Graves's disease, and may never develop that condition. This group, to which the term "masked hyperthyroidism" has been applied, consists of patients in whom the heart is affected as a result of thyrotoxicosis. They are essentially heart patients and present themselves for examination complaining only of cardiac symptoms. Parkinson and Cookson,[1] from an investigation of the size and shape of the heart in goitre, cite a few cases lacking the classical symptoms of thyrotoxicosis, but with the main symptoms and signs cardiac; they are regarded as belonging to the group of masked hyperthyroidism. The diagnosis is often difficult to make, and at the present time we must be prepared to consider an assemblage of indefinite symptoms and signs. The symptoms point to the heart; the heart always shows some abnormality, and as a rule no other ætiological factor is present to account for the condition.

This investigation was begun as the result of the observation that certain patients, who for long periods had attended out-patient clinics complaining of attacks of palpitation without apparent cause, later and unexpectedly, developed signs of thyrotoxicosis. A search was then instituted for similar cases in which a dysfunction of the thyroid was giving rise to cardiac symptoms in association with minimal signs and symptoms usually associated with thyrotoxicosis. Selected patients have been observed over periods of nine to twelve months, many as in-patients and the remainder periodically as out-patients. Electrocardiograms have been taken at intervals and observations on the heart size have been controlled by orthodiagrams.

An attempt has therefore been made here to describe the cardiac and associated symptoms and signs, and to build up some sort of symptom-complex which may be more easily recognised. The importance of the condition is apparent on account of its relative frequency, its difficulty of diagnosis, and finally its amenability to treatment. For the sake of brevity only a few cases are described in this paper, but in the 15 patients observed the diagnosis has been justified by the results of appropriate medical or surgical treatment, and by the estimation of the basal metabolic rate. It may be mentioned in addition that several patients were seen in whom the cause of symptoms was an associated thyrotoxicosis although another pathological condition was present—e.g., hypertension.

As long ago as 1885 Charcot[2] described cases of the "maladie de basedow, formes frustes" in which one of the triad—tremor, struma, or exophthalmos—was not present. In 1887 Chvostek[3] divided these cases into three groups, one of which he called the monosymptomatic group. Levine and Sturgis[4] in 1924 described five patients all of whom had been treated for a number of years as primary heart disease. They showed that cardiac symptoms may be the only ones present in thyrotoxicosis, and stated that in the absence of the classical triad the diagnosis must be made on less obvious signs. All their patients were between 38–64 years of age, all complained primarily of cardiac trouble, all were alert, overactive, and with animated facial expression. Again, Levine and Walker [5] in 1929 stressed the fact that the thyroid gland may remain toxic for years without any sign of exophthalmic goitre, and yet affect the heart; and they mentioned that the degree of toxicity of the gland may vary from time to time. The prognosis if treated by iodine, followed later by operation, was said to be good, even when anasarca is present.

Hamburger and Lev [6] in 1930 reported five cases, all in patients past middle life, who were of apathetic appearance in direct contrast with the first series of Levine and Sturgis. Freund and Cooksey [7] noted the difficulty of diagnosing thyroid toxicosis in elderly patients as they rarely show any thyroid enlargement, and they reported five cases, watched for at least 18 months.

PATHOLOGY

The pathological changes in the heart brought about by thyrotoxicosis are the subject of much controversy. The three questions which arise in connexion with this problem are:—

(*a*) Firstly, the question as to whether dysthyroidism produces macroscopic changes in the heart, i.e., increase in size and increase in weight, when all other causes can be excluded. Opposing views are held by various authors. Parkinson and Cookson [1] state that in a series of 43 necropsies in goitre cases, about 50 per cent. showed cardiac hypertrophy, and in their clinical series in which the size of the heart was measured by X ray, 45 per cent. showed some enlargement. The younger patients and those with a shorter duration of symptoms showed no hypertrophy. The average heart weight was greater in those patients with established fibrillation than in those with a normal rhythm.

Hurxthal [8] found hypertrophy to be rare, and when it was present he ascribed it to coexisting cardiovascular disease. Hurxthal, Menard, and Bogan [9] were of the same opinion, and Rosler [10] found no departure from the normal size in the majority of his patients. Again, Lahey [11] expresses the view that when failure occurs in goitre it is due to the effect of thyroid toxæmia on a previously damaged heart. Hermann and F. Wilson [12] studying the ratio of ventricular weight to body-weight in a series of cases found this to be 0·00292, which is normal.

Table I. illustrates the size of the heart in 15 cases, as measured by orthodiagram. The method of measurement used is that of Dietlen, and though it is not put forward as an infallible method, the figures may be quoted.

In considering this table, it will be seen that in only two cases (Nos. 1 and 14) was there notable enlargement: in the former cardiac failure was present, whilst in the latter gross myocardial changes were revealed by electrocardiogram. Of the remaining five patients in whom the heart was enlarged, in three the enlargement was minimal. It must be borne in mind also that the average age of the series was 52 years, and that therefore no comparison can be made with measurements in series of cases of Graves's disease in whom the average age is, as a rule, much lower.

Only one patient died (Case 15), a woman aged 57, who had been the subject of attacks of paroxysmal auricular fibrillation for three years. In this case teleradiograms showed a very slight enlargement and this observation was later confirmed at autopsy, though the weight of the heart was only 9¼ oz. Another patient (see Case 2), a woman aged 57, had constant tachycardia of 120 for two and a half years and yet clinically and by X ray showed no enlargement of the heart.

TABLE I.—*Size of the Heart*

Case.	Transverse diameter of		E., P. or A.	Case.	Transverse diameter of		E., P. or A.
	heart.	chest.			heart.	chest.	
	cm.	cm.			cm.	cm.	
1	16·0	22·5	Yes	9	10·5	21·0	No
2	11·0	22·3	No	10	13·3	22·2	Yes
3	12·0	23·0	No	11	10·0	21·0	No
4	12·0	21·5	Yes	12	10·5	23·1	No
5	11·5	21·0	Yes	13	11·4	22·2	No
6	12·2	25·6	No	14	14·0	22·5	Yes
7	11·5	21·1	Yes	15	12·0	21·2	Yes
8	11·8	22·5	No				

E., P. or A.= enlargement, present or absent.

(*b*) The second question is whether microscopic changes are found in the heart in patients who die after showing cardiac symptoms. Again varying opinions are held. Goodall and Rogers [13] state that definite pathological changes can be seen under the microscope and that these changes are those of myocardial degeneration. Goodpasture,[14] Wilson,[15] Johnson,[16] and others also describe actual changes in the muscle-fibres themselves. Willius, Boothby, and Wilson,[17] however, hold the view that the post-mortem evidence is unconvincing and that "at necropsy insufficient evidence is disclosed to ascribe death to cardiac causes . . . ."

(*c*) Finally, if the changes described above do exist, naked-eye or microscopic, are they characteristic of thyroid disease? At the present time the answer to this question must be that they are not.

CARDIAC SYMPTOMS

Palpitation is the most constant symptom; and this is not commonplace palpitation, but is something which even in a sensible patient constitutes a genuine and besetting illness. All in this series complained of such attacks as their main symptom; one had frequent attacks for 11 years, another for 10 years, and the average duration throughout a series of 15 cases studied is 3⅔ years. The character of the attack of palpitation varies according to the heart action on which it is based; this may determine the method of onset and cessation, the exciting factors, and the duration of the attack.

The commonest objective basis for the attack is a simple tachycardia with which may be associated extrasystoles. In this type of case the palpitation may occur very frequently, many times in the 24 hours, be gradual in onset and offset, and be precipitated by exertion and emotion and relieved by rest. The presence of extrasystoles with a rapid pulse-rate, when these irregularities might be expected to disappear, is so often observed in these patients and is so unusual in other cardiac conditions that it may be of value in pointing to the thyroid as the ætiological factor. In view of the above observation, the extrasystole may assume a greater significance, but only in a patient suffering from attacks of palpitation in whom no other pathological lesion can be shown as the cause. In other words, it may be said that extrasystoles in association with a rapid pulse-rate in a patient suffering from attacks of palpitation for which no other cause can be found suggest that the thyroid gland is culpable.

Paroxysmal auricular fibrillation is another arrhythmia commonly associated with the condition and giving rise to the attacks; in these cases the palpitation is not so frequently recurrent as in the simple tachycardia with extrasystoles just described. The attacks are much more sudden in onset and offset, they occur at varying intervals, but seldom daily, and they are independent of exertion or emotion. These attacks may occur for a number of years and later be followed by an established fibrillation. Parkinson and Campbell[18] found 15 per cent. of 200 cases of paroxysmal fibrillation to be goitrous in origin. They further state that "the realization that goitre in almost any of its forms may be the cause of these paroxysms is of great importance." As has been said,[1] in patients without any ocular or nervous disturbances usually associated with thyroid dysfunction, fibrillation may result from the toxic action of a "very small or imperceptible goitre." Levine and Sturgis's[4] five cases all had paroxysmal fibrillation. Since the underlying cause is a toxic effect on the myocardium, it is reasonable to assume that any of the arrhythmias may occur. The type of arrhythmia present in the 15 patients studied was as follows:—

1. Simple tachycardia	4
2. Simple tachycardia with extrasystoles	4
3. Paroxysmal fibrillation	4
4. Ventricular extrasystoles in runs	1
5. Established filbrillation	2

Breathlessness, alone and apart from palpitation, is not a common presenting symptom unless the patient is not seen, or the condition is not recognised, until failure is present.

The association of anginal pain with thyrotoxicosis has been noted. Lev and Hamburger[6] reported cases, and Levine and Walker[5] consider that in these patients coronary artery disease must coexist, and that the added strain on the heart of a thyrotoxicosis renders its blood-supply insufficient and pain results, comparable in its method of production with the pain of angina of effort.

In the 15 cases of masked hyperthyroidism studied, the average age of which was 52 years, five patients gave a history of pain in the chest. In three the description of the pain was characteristic of angina pectoris; it was substernal, dull and heavy in character, and of a minute or two's duration only, and in all three its onset always coincided with the onset of an attack of palpitation.

CARDIAC SIGNS

Cardiac overaction is constantly present. It is usually, but not constantly, accompanied by tachycardia. Its presence may be detected in several ways. The character of the apex impulse is the most useful guide; on palpation it is found to be altered and the first impression which is given immediately is that the heart is abnormal. It is "sudden" in character—i.e., it is a short, quick, rather forcible impulse, and gives the impression that the organ is enlarged, although the impulse may be in the normal situation. This apex impulse is quite unlike the forcible, sustained heave of that in hypertension, but is similar in character to the apex-beat of the normal heart immediately after exertion or emotion.

The examination of patients was always carried out after they had been lying at rest for at least half an hour. In addition the cases were seen and examined often, and were thus accustomed to the routine, so that the element of excitement and exertion were as far as possible eliminated.

This "suddenness" of the apex-beat with the patient at rest, and even when the rate is slow, is of the greatest diagnostic importance. There may, in addition, be a systolic thrill at the apex.

Van den Bergh[19] emphasises the importance of cardiac overaction and considers it a most helpful sign because of its constancy in practically all cases of goitre toxicity.

Auscultation will usually reveal the first sound at the apex to be altered in character. It is louder, shorter, and slightly higher pitched than normal—it may be a little "blurred" so that a presystolic murmur is simulated. A short systolic murmur may be present; this murmur being oftenest maximal in the pulmonary area, where the second sound is often accentuated. Extrasystoles are commonly heard, sometimes in runs, or they may be so frequent as to render the rhythm most irregular.

Electrocardiographic examination, apart from recording the type of arrhythmia, has not proved of great help in diagnosis; occasionally the size of the P wave has been increased and has equalled that of the T wave, especially in lead II.

Radiography of the heart has proved of value. On looking at the heart as a whole, it is usually seen to be little or not at all enlarged and smaller than the clinical examination would lead one to expect. The next feature to be noted is that the organ is overacting; pulsation is much increased. The extension of the beat is seen to be increased and is greater than that seen in a normal heart after exercise. The pulmonary arc may be fuller than normal and thus produce a straight left border to the heart shadow; pulsation in the pulmonary arc may be very much increased; the shadow of the superior vena cava may appear prominently.

Finally, on turning the patient into the first oblique position, the straight posterior border with no enlargement of the left auricle is in striking contrast to the shadow seen in mitral stenosis, from which condition masked hyperthyroidism has often to be distinguished.

As the condition occurs most often in older people, the typical "thyroid heart" is less commonly seen, and associated aortic atheroma or slighter grades of raised blood pressure may modify the picture.

EXAMINATION OF THE THYROID GLAND

When it is known that a cardiac abnormality exists, and when, from the cardiac symptoms or signs, attention is directed to the thyroid, examination of the gland will sometimes show the following. There may be no enlargement of the gland, and this may be so in a thin person in whom any enlargement, with the exception of a retrosternal one, would be easily visible. In distinction from this group, there exists a group of individuals with short fat necks in whom it is debatable whether the gland is increased in size or not. There may be no increase in the size of the gland, but the consistency appears to be altered, so that the gland is very firm on palpation. This hardening of the gland may be unilateral. The gland may contain one or more small hard nodules, which are so significant though they may not have been considered as the cause of the cardiac condition.

The size of the thyroid gland in 15 patients under observation was as follows:—

Group 1.—No visible enlargement	10
" 2.—Slight diffuse enlargement	1
" 3.—Moderate diffuse enlargement	1
" 4.—Visible nodule in the gland	3

In group 2 the case did not show any enlargement of the gland until ten years after the onset of the symptoms, although she was repeatedly examined with the possibility of thyrotoxicosis in mind.

ASSOCIATED SYMPTOMS AND SIGNS

Tremor is present in the majority. In this series all had a tremor of the fingers. A fine tremor only is of value as a sign of masked hyperthyroidism, as in the type of patient in which the condition is most commonly found, an elderly female, a coarse tremor can be of no diagnostic importance. Exophthalmos, on the other hand, is rarely present; in this series none of the patients showed it. In two cases a slightly "staring" expression was noted. The presence of von Graefe's sign without exophthalmos was seen.

The state of nutrition of the patient.—An interesting fact about the condition is the slow loss of weight which the patients experience. Most of them do lose weight at some period, but this loss is rarely noted by the patient herself, and I have never had the information volunteered in the history. Loss of weight in bed with appetite unimpaired may be of diagnostic value. Some of the patients studied are well above average weight for their height and some are obese. A few have not lost weight at all.

It will be seen from the foregoing description that patients actually suffering from thyrotoxic action on the heart may have no enlargement of the gland and no exophthalmos, may be fat and apathetic, and may lose weight very slowly or not at all.

Less obtrusive symptoms and signs.—It is, then, necessary to make a search for less obtrusive signs and symptoms, which if found to be present, point to the thyroid gland as the primary factor. Most of such signs or symptoms are elusive and are valueless singly, but if several are present together, in association with the cardiac signs, they may be of great value.

Flushing and moistness of the skin is often apparent. This flushing of the skin may give rise to a "salmon hue" mentioned by Levine and Walker[5] which, though difficult to describe, is often present and is of use as a diagnostic sign. Pigmentation of the skin, a light brownish patching occurring round the base of the neck and on the shoulders is described; it was seen in three patients. It is associated with a feeling of warmth, which is almost always present, and which is often mentioned by the patient herself; actual sweating attacks are not so commonly present. Unexplained attacks of diarrhœa are suggestive. Increased nervousness, and in particular a quickness of movement and a "fidgetiness," should not be overlooked. Premature greyness of the hair, lassitude, vomiting attacks, and sleeplessness all occur and should be noted. The general impression given by the patient is very important from the diagnostic standpoint.

THE BASAL METABOLIC RATE

The presence of a raised basal metabolic rate is of great value in confirming the diagnosis of masked hyperthyroidism; but since the toxicosis is often of very long duration and low grade, the high reading seen in frank exophthalmic goitre are not to be expected, and indeed were not seen, in this short series of patients. It must be borne in mind that in certain healthy individuals the rate is subnormal, and should such a patient develop a low grade of thyroid toxicity, metabolic rate estimation may not be a true indication of the amount of that toxicity. Again, it seems reasonable to suppose that the toxicity of the gland may vary from time to time and that one or more estimations of the rate may happen to be taken at times when the toxicity is low.

Morris[20 21] describes seven cases, all with a normal or subnormal metabolic rate, and all of which improved after thyroidectomy in the same way as did those with a raised rate. He states that operation either raises the rate when it is subnormal, or if it is normal leaves it unchanged.

Waters and Williams,[22] in recording a series of cases of menorrhagia due to hypothyroidism, mention three cases in which the rate was found to be normal, but in which there were other signs of thyroid deficiency which were relieved by the administration of gland extract. They emphasise that alterations in the metabolic rate should be accepted as only one of the signs, and not the essential criterion of a functional change in the gland.

Of the patients whom I have studied, the majority have shown a raised metabolic rate, but it may be mentioned that some had a normal or only very slightly elevated rate, though the symptoms appeared to be comparable with those in whom the rate was raised. At the present time, however, there is not sufficient evidence to form any definite opinion in regard to this problem, and further work in regard to it is in progress.

THE COURSE OF THE DISEASE

It seems possible to divide the cases into two groups in regard to the course taken by the disease.

(1) In the first group, the symptoms complained of—palpitation, sweats, and weakness—have been constantly present, but have not varied much in intensity, and apart from increasing weakness, the patient's state has been unaltered for long periods of time. A good example of this group is Case 2.

CASE 2.—Mrs. A., a woman aged 59, was admitted to hospital in August, 1931, complaining of palpitation and shortness of breath. The palpitation had been present constantly for two and a half years and during this period she had been in bed the greater part of the time, and had never been out of her house. The slight stimulus of getting out of bed accentuated the rate and this took several hours and often days before it settled down again. She had gradually lost weight and become weaker. Her skin was always moist, and she said she had become more nervous. There was no history of rheumatic or spirochætal infection.

Examination.—A thin woman, flushed moist skin, apathetic in appearance. Fine tremor of the fingers, no trace of exophthalmos or of enlargement of the thyroid, measurement around the base of the neck was 13 in., but the gland, though not at all enlarged, was unusually firm in consistency. Blood pressure 160/95. X ray showed a heart not enlarged, aortic arch slightly dense, and pulmonary arc slightly full. The apex-beat was "sudden" in the fifth space, there was a systolic murmur at the apex and base, but no other abnormality. When first seen the rate was 150, regular. She was given Lugol's iodine for 14 days and the rate fell to 100–110. The iodine was stopped and it rose again to 120. Eight days later iodine was again given, but no effect on the rate was noted. After a further 13 weeks in hospital the rate remained constant at 120, with occasional rises to 140–150 on exertion. Estimation of the basal metabolic rate at the end of this period was +37. Weight on admission was 7 st. 9 lb., 17 weeks later it was 7 st. 8 lb.

Here the thyroid was not enlarged at all, there was no exophthalmos, and only a fine tremor on which to suspect the thyroid as the causative factor. The condition was quite unaltered after 17 weeks rest in bed in hospital.

Exhibition of iodine at first had an effect on the rate, but later failed to do so. All other treatment had failed. The appearance of the patient was not in any way suggestive of hyperthyroidism and her only symptoms were cardiac. The condition, as mentioned above, had been present for two and a half years. On March 5th, 1932, the operation of *partial thyroidectomy was performed.* The patient recovered well from the operation, and ten days later the pulse had fallen to 80; it had never previously been at this level during the three years in which she had been under observation.

In September, 1932, five months after operation, she was perfectly well. Her tremor and nervousness had disappeared, the pulse had remained at an average level of 80, and she had gained 1 st. 8 lb. in weight. Her basal metabolic rate on Sept. 10th, 1932, had fallen to −8.

This case illustrates the failure of rest in bed to relieve the symptoms. This was true of all the patients seen. It also illustrates very well the "refractory" period which the patients show to iodine medication. The absence of cardiac enlargement after long-continued tachycardia is also notable.

(2) In the second group may be placed patients in whom the symptoms are recurrent and intermittent; thus frequent attacks of palpitation are complained of and these have been occurring over a period of months or years; into this group fall the majority of the cases observed. The intensity of the symptoms varies, and this is perhaps properly explained by variations in the toxicity of the gland. Thus the attacks of palpitation may occur at frequent intervals for a period of six or seven months, may then gradually become less frequent, cease altogether for a like period, and then start again.

The following case is a good example of this second group:—

CASE 13.—Mrs. B., a married woman aged 47, has attended the out-patient department of the National Heart Hospital since May, 1929. She complains of palpitation coming on in attacks which start quite suddenly, often in bed, and which awaken her from sleep. They last up to two hours and cease as suddenly as they start. She also has palpitation, slight dyspnœa on exertion, a dull præcordial ache, sweats, and attacks of diarrhœa which last for several days. She has become increasingly nervous. There is no history of acute rheumatism in early life, and the Wassermann reaction is negative. She says that the attacks of palpitation occur many times in one week on occasion, and at other times she may be free from the attacks for several weeks or months. In the intervals between series of attacks she feels well. These symptoms have all been present for about three years, and at their onset she had much worry over the illness of her husband. During the first years of attendance, the average pulse-rate was 100, and her weight varied between 8 st. 4 lb. and 8 st. 10 lb.

A tired-looking woman with flushed, moist skin and a faint brownish pigmentation over the right shoulder and the back of the neck, which she is quite certain was not present two years ago. Pulse-rate 104 regular, blood pressure 170/70, fine tremor of the fingers, no exophthalmos, no thyroid enlargement. Apex impulse typically sudden in the fifth space, internal to the mid-clavicular line, first mitral sound accentuated, but not "blurred," soft systolic murmur at all areas. Electrocardiograms showed simple tachycardia; unfortunately no attack of the severe palpitation which awakened her in the night was recorded. X ray examination showed an over-demonstrative heart, not enlarged, with no increase in size of the pulmonary arc; the aorta was slightly increased in width. The basal metabolic rate was +47. During a course of iodine for four weeks her symptoms improved. The pulse-rate became slower (80) and her weight rose from 8 st. 8½ lb. to 9 st. 3 lb. Coincident with this improvement in symptoms, however, the thyroid which had never been enlarged became definitely full. This improvement lasted for six weeks when the symptoms again became worse, the palpitation started again as also did the diarrhœa, her weight, however, remained constant. Her condition is to-day unchanged. She refuses any operative treatment.

DIFFERENTIAL DIAGNOSIS

Since the diagnosis of the condition may present great difficulty, the differential diagnosis is naturally difficult.

Mitral stenosis is a condition which may closely simulate masked hyperthyroidism. In both the first sound in the mitral area may be loud, and in thyrotoxicosis it may be blurred and closely suggestive of a presystolic murmur, and in both the pulmonary second sound may be accentuated. In both an apical systolic murmur is often to be heard. A history of acute rheumatism in childhood may be of help, but its absence does not exclude the former diagnosis. If fibrillation is present the differentiation of the two diseases becomes even more difficult, as they are the very two which often induce this complication.

The diagnosis can often be made upon: (1) The presence of associated signs of thyrotoxicosis, slight though they be. (2) The X ray appearance of the heart. The latter is often most useful. If the case is one of masked hyperthyroidism, the heart will commonly be smaller than the clinical examination would indicate it to be; the left border would appear straight, due to a filling out of the pulmonary arc, and the whole heart would be actively contracting and over-demonstrative. Lastly, and of most importance in differentiation is the size of the left auricle as seen in the first oblique position after the administration of barium. It is usually enlarged in mitral stenosis and never in thyrotoxicosis.

If a right axis deviation or a wide, split P wave is present, the electrocardiogram may be of value in negativing the diagnosis of thyrotoxicosis. I have not found it to be of use in confirming this diagnosis.

The following case illustrates the difficulty of diagnosis between the two conditions:—

CASE 3.—Mrs. C., a woman of 42, admitted to hospital in April, 1931, with a history of attacks of palpitation for about 16 years, a dull præcordial ache, and shortness of breath on exertion for four years. There was no history of rheumatic fever, but she suffered from severe growing pains and frequent tonsillitis as a child. The pulse was very irregular with a rate of 90–100, rising to 130–140 with the slightest exertion or excitement. She stated that she had not lost weight, and when under observation—March, 1931, to April, 1932—her weight varied by 5 lb. only. Physical signs were as follows:—

Apex impulse in the fifth space just external to the mid-clavicular line, no thrill, first sound at the apex very loud and "blurred," ? presystolic murmur, and there was a systolic murmur, soft in character, and not well propagated. At the pulmonary area the second sound was loud and short. Electrocardiogram showed a sinus rhythm with very frequent ventricular extrasystoles. Blood pressure 135/80. A provisional diagnosis of mitral stenosis was made, but X ray examination showed the heart to be not enlarged, over-demonstrative, with a prominent pulmonary arc which pulsated very markedly, and the left auricle was not enlarged as it would have been had the diagnosis been correct. On further questioning she stated that she suffered from profuse sweats on the slightest exertion and that her skin was always moist; she was flushed and had a fine tremor of the fingers; there was no exophthalmos. There was no noticeable fullness of the thyroid gland, but the right lateral lobe was denser in consistency than the rest of the gland. There was no improvement after seven weeks' rest in bed with digitalis therapy. The basal metabolic rate was then estimated and found to be +30, and she was greatly improved by a short course of iodine, the rate dropped to 80, and the extrasystoles became less frequent. Later she relapsed again and a second course of iodine was given without result. As she refused to undergo operation, she was then given five applications of X rays to the gland at fortnightly intervals. As the result of this procedure she is very greatly improved and her basal metabolic rate has fallen to +16.

Raised blood pressure is another factor which tends to complicate the diagnosis of masked hyperthyroidism. It is an established fact that thyrotoxicosis alone alters the blood pressure, usually raising the systolic pressure, leaving the diastolic unaltered or even slightly lowered, and thus increasing the pulse pressure. Many clinicians to-day regard this increase in the pulse pressure as one of the most important diagnostic features in thyrotoxicosis. In masked hyperthyroidism the significance of the blood pressure is more difficult to assess, for the condition is found to occur in older people, the average age of the patients studied being 52 years, in whom the pressure is normally higher, and with moderately raised pressures it is very difficult to say how much of this hypertension is secondary to the thyrotoxicosis and how much is primary. With a high systolic pressure the fact that the diastolic pressure is little raised and the pulse pressure great is certainly of paramount importance in coming to a decision at this point.

In this connexion the following two cases are of great interest:—

CASE 4.—Miss D., aged 57, was first seen complaining of palpitation, nervousness, headaches, and sweats. The symptoms had been present for one year, and in that time she had lost 12 lb. in weight. She stated that a swelling had been present in the neck since the age of 21. Examination showed a highly nervous patient with a moist flushed skin and a fine tremor of the fingers. There was a small, indefinite mass in the right lateral lobe of the thyroid gland which was not visible. The pulse-rate averaged 88 at rest and rose with slight exertion to 120. A soft systolic murmur was present at all areas. The mitral first sound was very loud and the aortic second sound a little accentuated. The blood pressure was 220/110. The electrocardiogram showed a well-marked left ventricular preponderance, and X ray a little enlargement of the left ventricle with a slightly wide aortic shadow.

She was admitted to hospital and treated as a case of hypertension, but after nine weeks in bed her symptoms were in no way altered; the blood pressure had fallen to 190/95. She was discharged and when seen again two months later her condition was unchanged. The pressure was then 220/105. After a further two months the operation of hemithyroidectomy was performed. Six weeks later she was much improved, her pulse-rate was 76, her palpitation, nervousness, and tremor had all gone; to-day, apart from occasional headaches, she is quite well. She has gained 1 st. in weight. Her blood pressure, however, is still 220/120.

TABLE II.—SHOWING THE IMPORTANT FEATURES OF FIFTEEN CASES

No. of case.	Sex.	Age.	Duration of symptoms in years.	Palpitation.	Alteration in rhythm.	Enlargement of thyroid gland.	Exophthalmos.	Nervousness.	Sweating.	Pigmentation.	Diarrhœa.	Tremor.	Loss of weight.	Pain in chest.	Blood pressure.	Enlargement of the heart.	Basal metabolic rate.	Cardiac failure.

S.T. = Simple tachycardia; Ex.S. = Extrasystoles; P.A.F. = Paroxysmal auricular fibrillation; E.A.F. = Established auricular fibrillation; P.V.T. = Paroxysmal ventricular tachycardia; Sl. = Slight.

CASE 5.—Mrs. E., a woman aged 42, who had previously attended the hospital as an out-patient for 18 months, was admitted in July, 1931, complaining of attacks of palpitation brought on by exertion or emotion, and lasting for about an hour. They were of very frequent occurrence, several such attacks in the 24 hours was common. She also complained of sweating attacks in bed at night, a cough in the winter time, and rapid fatigue. These symptoms had been present in varying degree for five years. Five years ago she had considerable worry in her home life. During the two and a half years prior to her admission she had been in another hospital twice on account of her palpitation. There was no previous history of rheumatism.

Examination showed a well-nourished woman, rather apathetic in appearance, with flushed, moist skin, no exophthalmos, fine tremor of the fingers, and no noticeable enlargement of the thyroid gland, measurement around the base of the neck being 13 in. Palpation of the neck revealed an increase in density of the right lateral lobe of the thyroid, and the patient herself volunteered the information that she felt at times that she must swallow to move something.

The heart was not clinically enlarged, though the apex was sudden and shock-like. Mitral area, first sound accentuated and blurred, very suggestive of a short presystolic murmur; soft systolic murmur. Pulmonary area, second sound accentuated; soft systolic murmur; the second sound in the aortic area was also accentuated. Blood pressure was 240/130. Eighteen months before, in January 1930, it was 150/100. The pulse-rate was 92 and varied between this and 120 during her stay of 11 weeks in hospital. Electrocardiograms showed the attacks of palpitation to be due to a simple tachycardia; a few extrasystoles were present. During her period of attendance as an out-patient she had not lost weight.

The diagnosis was for some time in doubt, the doubtful presystolic murmur and the accentuated pulmonary second sound suggested the possibility of mitral stenosis combined with hypertension, but X ray examination showed a heart not enlarged, with no increase in size of the left auricle, over-demonstrative with a full pulmonary arc. The basal metabolic rate was then found to be +36. She was later operated upon, in September, 1931, and the right lateral lobe of the gland removed. Embedded in its substance was an "adenoma" with a surrounding area of hyperplastic gland tissue. She made a very good recovery, and when last seen, three months after the operation, was very much improved and the palpitation was gone. The pulse-rate was 80. The metabolic rate had fallen to +13. The blood pressure was still 230/125.

The points of interest in a study of these two cases are: (1) That although both had a raised blood pressure, the symptoms which were relieved by operation were due to the associated thyrotoxicosis. (2) That the removal of the toxic thyroid did not influence the blood pressure. Further, in both the diastolic pressure was high. White,[26] in describing a series of cases of tachycardia due to hyperthyroidism without obvious goitre, mentions one case with a high blood pressure, in whom operation relieved the symptoms, but left the pressure unaltered.

The differential diagnosis between masked hyperthyroidism and *pulmonary tuberculosis* may occasionally give rise to difficulty. In both conditions sweats and loss of weight may occur and in both the patient may be languid, listless, and weary looking, but in the former condition cough is uncommon, as is also a raised temperature. Another point of distinction is the fact that in thyrotoxicosis the tachycardia persists after a long period of rest in bed.

Tucker[24] records a case in which a diagnosis of pulmonary tuberculosis was made and later changed to thyrotoxicosis, the basal metabolic rate being +35 and the patient responding well to iodine therapy.

The symptomatology of the condition may rather closely resemble that of *effort syndrome* so commonly seen in soldiers in the late war, and said by many to be still of frequent occurrence amongst civilian populations; but masked hyperthyroidism occurs notably in older patients and in a different type of individual to the latter condition. Most of the patients in this series were in the fourth. fifth, or sixth decades. Foster[25] points out the difficulty of diagnosis between *neurocirculatory asthenia* in young adults with an adolescent goitre and thyrotoxicosis, and says that the subsidence of the tachycardia in sleep is of use in differentiating the two conditions.

Hamburger and Lev[6] describe one case which closely simulated *diabetes mellitus with hypoglycæmic shock* following insulin medication, but which was relieved by iodine and thyroidectomy.

SUMMARY AND CONCLUSIONS

This paper is an account of the investigation of 15 patients, all of whom may be described as cases of hyperthyroidism masked as heart disease. All presented themselves complaining of cardiac symptoms; all were women; and the average age was 52 years. The average duration of symptoms was 3·8 years. The majority were apathetic in appearance, of good nutrition, and quite unlike the classical picture of Graves's disease. The diagnosis was indicated by the cardiac condition, and the factors which pointed to it were:—

(1) "Suddenness" of the apex-beat, even when the rate was slow, suggesting an increase in the size of the heart, which was not present in the majority. The apex impulse may be likened to that given by a normal heart after exercise.
(2) Presence of extrasystoles with a rapid rate.
(3) Presence of paroxysmal auricular fibrillation.
(4) The X ray appearance of the heart.
(5) Increase in the pulse pressure.

It was confirmed by the presence of less obtrusive associated symptoms and signs of which tremor and moistness of the skin are the most constant and were present in all of this series.

Thyroid enlargement was absent in ten patients in the series. in two a very slight fullness was noted only when the patient was made to swallow in the sitting posture, and in a further two a dense calcified nodule was present, though its significance had not been recognised.

Exophthalmos is rarely seen in this condition. but in two cases a slightly staring expression was noted. Pigmentation of the skin was seen in three cases. Some loss of weight occurred at some time in the majority but was never marked, and its occurrence was never volunteered by the patient. Its presence is not essential in the diagnosis.

Estimation of the basal metabolic rate is of great value if it is found to be raised as a means of confirming the diagnosis. The majority of patients seen had a raised rate, but several cases were studied with a normal or only slightly raised rate in whom the clinical picture and the response to treatment were comparable with patients in whom the rate was raised.

The association of pain in the chest of anginal nature and thyrotoxicosis is discussed. Five patients in whom this occurred are mentioned; in four the pain was felt at the onset of the attacks of palpitation, and as the latter were the result of thyroid toxicity, and appeared to precipitate the pain, such pain must be regarded as a symptom of this condition. Its frequency in this series can be explained on the grounds of the age-incidence—i.e.. an age at which atheroma of the coronary arteries is commonly present. The thyrotoxicosis must then be regarded as an ætiological factor of the pain only in as much as it leads to an increased demand for work on the part of the heart, in the same way as does exertion or emotion.

Two cases are described in which high blood pressure was present, but in whom the symptoms were due to an associated thyrotoxicosis. In both operation entirely relieved the symptoms, but left the pressure unchanged.

Of great value in diagnosis are the failure of rest and digitalisation to affect the condition. Iodine is often of value as a therapeutic test when it is first given. This effect. though often striking, was always transitory, and later the drug had no effect. The patient appears to become refractory to it.

A plea is made for the earlier recognition of these cases on the grounds of: (1) their comparative frequency; (2) their difficulty of diagnosis; and (3) their amenability to treatment.

The important features of the cases studied are set out in Table II.

My thanks are due to Dr. John Parkinson who proposed this investigation and who has given me much advice and help throughout; to the members of the honorary staff of the National Hospital for Diseases of the Heart for permission to study the patients under their care; and to Prof. E. C. Dodds and Dr. J. D. Robertson for their kindness in estimating the basal metabolic rates.

REORGANISATION OF ST. CHAD'S HOSPITAL, BIRMINGHAM.—This hospital which, although it is owned by a company, limits its dividends to a maximum of 6 per cent., profits beyond that amount being used for improved equipment, has recently been reorganised. There is still a resident medical officer, with a full nursing staff, but there is no longer a medical staff. Under the new scheme patients are received from. and attended by, any doctor, whether consultant or general practitioner. There is a uniform charge of five guineas in a ward or in a single room, as desired; there is a maximum charge of one guinea for the use of the theatre. The doctors fix their own fees, which are paid to them direct. The hospital accommodates from 80 to 85 patients.

THE ANÆMIA OF CARCINOMA OF THE STOMACH

By Stanley J. Hartfall, B.Sc., M.D. Leeds, M.R.C.P. Lond.

MEDICAL ASSISTANT, GUY'S HOSPITAL; LEVERHULME RESEARCH SCHOLAR, ROYAL COLLEGE OF PHYSICIANS OF LONDON

The treatment of the anæmia of malignant disease has not been studied with the same intensity as that of other less fatal anæmic states. In the desire to treat the primary lesion little attention, as a rule, is directed to the condition of the blood. The anæmia is regarded as a secondary manifestation, often as part of the malignant cachexia, and is allowed to take its course untreated. There are, however, important exceptions to this general statement, and, in operable cases, the surgeon who is anxious to make his patient "fit for surgery" takes steps, usually by means of transfusions, to combat anæmia if it be at all severe.

In early malignant disease anæmia is occasionally the presenting symptom, especially of obscure growths of the alimentary tract. There are two situations in which the primary lesion is likely to be found—namely, the colon, especially the ascending portion, and the stomach. Anæmia associated with cancer of the stomach is the concern of the present report. All my three cases presented as examples of severe anæmia with very little suggestion of gastric disturbance other than loss of appetite. All three at first offered considerable difficulty in diagnosis, and all, unfortunately, were inoperable—one on account of peritoneal and later intrathoracic metastases, another because of advanced age, and the third because of local infiltration into the liver. Nevertheless in each case the anæmia responded in a remarkable way to treatment in spite of the existence of the growth, and the improvement continued until some serious complication supervened. The changes in the blood were followed by daily observations in Cases 1 and 2; less frequent observations were made in Case 3.

Figs. 1 and 2 illustrate the changes in the blood (red corpuscles, hæmoglobin, and reticulocytes) in Cases 1 and 2 respectively.

THE FIRST CASE

Male, aged 55. Family history negative. He had never had a day's illness until the onset of the present illness about eight weeks before admission to hospital. He first noticed that he was breathless even after the mildest exertion, and was told by his friends that he looked pale and ill. He noticed increasing weakness, and complained of tingling in the fingers and toes. He made no complaint of disturbance of digestion other than that for the last month or so he had not the energy to eat. He had not noticed much loss of weight. On examination he showed marked pallor, the teeth were septic, the tongue normal. The central nervous system and other systems showed no abnormality except that the abdomen was a little full and there was slight discomfort on deep pressure to the right of the mid-epigastric region.

The blood count at this time was as follows: red cells, 2,000,000; hæmoglobin, 37 per cent.; colour-index, 0·66; reticulocytes, 3·5 per cent.; and white cells, 6000; the relative proportions being normal. The film showed the anæmia to be of the microcytic type, many of the red cells were slightly distorted in size and shape, and a moderate degree of polychromasia was present. During the period of investigation the patient was given half an ounce of liver extract and half a pound of whole liver daily, and this was continued for 13 days.

The presence of free fluid in the peritoneum, the development of a palpable tumour in the epigastrium, and a positive occult blood test strongly suggested carcinoma of the stomach. There was achlorhydria in the gruel test-meal with altered blood in nearly every sample, and X rays showed the filling defect of carcinoma at the pyloric end of the stomach. The Wassermann and the van den Bergh reactions were negative. The gastric juice secreted on histamine stimulation contained no free acid and scarcely any pepsin—i.e., 2 Grosse units (normal = 30 to 50 units).

At the end of the period on liver there was no improvement in the blood, the number of the red cells was unaltered, the hæmoglobin had fallen to 34 per cent., and the reticulocytes were 3·5 per cent., never having risen above 4·8 per cent. After an interval of three days, at the end of which the occult blood test was still positive, a mixture containing grs. 90 of iron and ammonium citrate a day was given. On the fourth day the reticulocytes reached 14·7 per cent., and on the sixth day a maximum peak of 17 per cent. was attained. On the eighth day the red cells were 3,040,000, the hæmoglobin 42 per cent., the reticulocytes had fallen to 5·7 per cent. The blood continued to improve, and 18 days after the commencement of treatment by iron the red cells were over 4,000,000, the hæmoglobin 66 per cent. From the eighth day the stomach had been washed out every morning. On the twenty-third day a considerable quantity of blood was present in the stomach, and the blood in the stools increased. Apparently a moderate hæmorrhage caused a cessation in the improvement in the blood (Fig. 1). The patient now developed a large pleural effusion due to intrathoracic metastases, and active treatment of his anæmia was allowed to lapse.

In this case the anæmia associated with carcinoma of the stomach was not affected by liver treatment, but following the administration of iron by mouth a reticulocyte crisis and a notable improvement in the condition of the blood occurred.

THE SECOND CASE

Male, aged 73. Family history negative. He had always been a healthy man until about 18 months ago when his bowels, previously quite regular, became a little constipated. Purgatives were taken which induced an attack of diarrhœa, and later diarrhœa sometimes occurred spontaneously. From about a year ago the patient became subject to bouts of nausea at long intervals, when he was off his food for several days, and periods when he suffered from flatulence after whatever he managed to take. His diet was largely farinaceous, for he developed a slight distaste for meat. These digestive symptoms were only elicited on careful questioning, for the principal complaint of the patient was his extreme weakness, while his friends said that he had become very pale and a shadow of his former self. He had in fact only lost about 6 lb. in weight.

On examination he was very pale but not wasted; he had 3,400,000 red cells, 40 per cent. hæmoglobin, colour-index 0·58, white cells 9800, the proportion of polymorphs being very slightly raised. Gastric analysis revealed achlorhydria in the gruel test-meal, histamine after lavage produced small quantities of free acid and pepsin, but both were much below the normal response. There were traces of altered blood in the gruel fractional test and in the stomach washings, and occult blood was present in the stools. The van den Bergh test was negative, as also was the Wassermann reaction. Radiography of the stomach showed a large filling defect extending along the pyloric canal.

During the period of investigation the patient had been given liver extract in full doses. The anæmia was of microcytic type with a moderate degree of polychromasia and anisocytosis. It was therefore not expected that the patient would respond to liver, but he was allowed to continue with it for eight days. At the end of this time the number of red cells was unaltered and the hæmoglobin had fallen to 36 per cent., as shown in Fig. 2. After four days' interval, at the end of which the occult blood test in the stools was again found to be positive, he was given iron in the form of Blaud's pill grs. 20 t.d.s., and from the fifth day the stomach was washed out every morning. A reticulocyte crisis occurred with a peak on the ninth day. The subsequent uninterrupted improvement in the blood can best be seen in Fig. 2.

Operation being refused on account of age the patient returned home, where he continued to improve for about three weeks. Then symptoms of pyloric obstruction developed, practically all treatment was stopped, and the patient rapidly went downhill and died.

In this case the anæmia of carcinoma of the stomach failed to respond to liver, but following treatment with iron a reticulocyte crisis and a remarkable improvement in the anæmia occurred.

THE THIRD CASE

A married woman, aged 42. She had been anæmic and weak for many months after each of three pregnancies. She, however, dated her present illness in an indefinite way from the birth of her last child one year ago. During delivery she lost more blood than usual, and was kept in bed two months with a white leg. Mild symptoms of indigestion were noticed about this time, chiefly fullness and distension in the epigastrium. She remained excessively weak and pale and was in fact an invalid. Three weeks before admission she had a bilious attack, was nauseated, and vomited. She subsequently had three similar attacks. Her weight had been steady. The periods had not reappeared since her confinement.

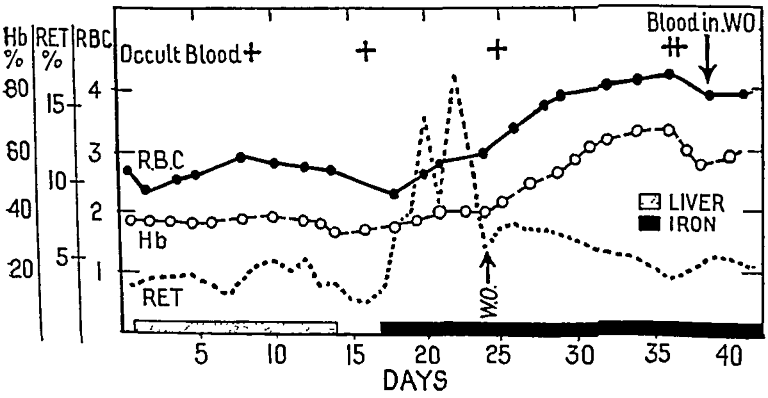
On examination she showed a waxy pallor of the skin with excessive pigmentation of the exposed parts and she was dyspnœic at rest. The heart, lungs, and central nervous system were normal. The tongue was smooth, the nails brittle, the spleen was palpable 1 inch below the ribs. The liver was enlarged downwards nearly 3 inches, a hard mass the size of an egg projecting from its lower edge to the right of the midline. The blood count showed the following changes: red cells, 2,720,000; hæmoglobin, 18 per cent.; colour-index, 0·33; white cells, 7200; the differential count being normal. The gruel fractional test showed achlorhydria; the juice secreted on histamine stimulation also contained no free acid, and the pepsin content was only equal to 3 Grosse units. The van den Bergh and the Wassermann reactions were negative.

The early investigations suggested a large gall-bladder with stones, adherent to the stomach and deforming it. Later the persistence of occult blood in the stools and the radiogram which showed a filling defect in the stomach led to a diagnosis of carcinoma.

During the period of investigation this patient was given Blaud's pill grs. 45 daily, and 1 drachm of acid. hydrochlor. dil. t.d.s. Within two weeks the hæmoglobin rose to 30 per cent., and on the twentieth day from the commencement of treatment by iron the red cells were 4,660,000, and the hæmoglobin was 45 per cent.; after another 14 days the latter had risen to 55 per cent., and the spleen could no longer be palpated.

This case with an anæmia of probably three years' duration, typical in its onset and progress of simple achlorhydric anæmia, responded in a dramatic way to large doses of iron in the presence of an inoperable carcinoma of the stomach.

FIG. 1



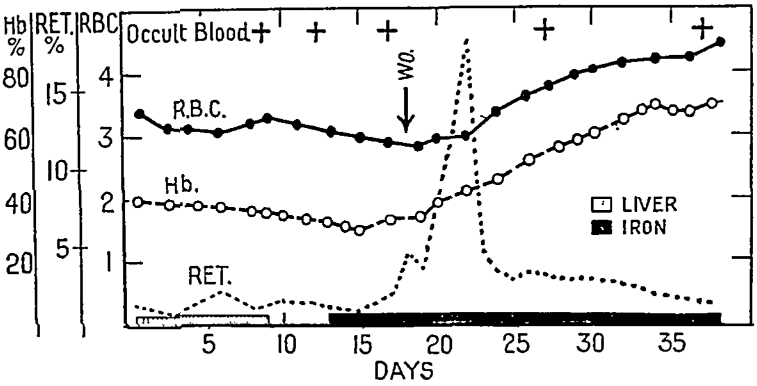
CASE 1.—Showing rapid effect produced by iron after a negative period on liver. WO = gastric washout.

DISCUSSION

These three patients illustrate how hypochromic microcytic anæmia associated with carcinoma ventriculi may respond in a remarkable way to large doses of iron. The severe gastric secretory defect is comparable with that of simple achlorhydric anæmia if contamination of the gastric juice with blood and exudate from the eroded growth surface be excluded.[1] Thus two cases were completely achlorhydric to both the gruel and the histamine tests, while the third showed only traces of free acid on histamine stimulation. All three had gross pepsin defect in the histamine secretion.

It is useful to inquire into the possible factors which cause early anæmia in certain cases of carcinoma of the stomach. One is obviously not concerned with the anæmia of the later cachexia, even assuming it has a different explanation, which is doubtful; or that due to gross hæmorrhage. In the type under discussion the following factors may, in varying degrees, play a part. (1) Repeated but quite small hæmorrhages from the surface of the growth, even in the earliest stages. The persistence of occult blood in the stools throughout the course of the disease is good evidence of this. (2) Defective nutrition from impairment of appetite, and reduced or modified intake of food defective in the necessary hæmatinic principles; in this connexion the common early symptom of distaste for meat is of special interest. (3) Defective gastric digestion due to disturbances in the gastric secretions. It is believed that changes in the gastric secretion associated with chronic gastritis antedate the development of carcinoma in nearly 75 per cent. of cases —i.e., those other than carcinoma *ex ulcere*.[2] Thus achlorhydria has been found years before the development of cancer of the stomach, and certainly achlorhydria and apepsia are present in the large majority of such cases once the lesion is established.

FIG. 2



CASE 2.—Showing negative result with liver and improvement following reticulocyte crisis induced by iron.

There are two well-defined blood diseases in which comparable gastric defect is present[3]; Addisonian pernicious anæmia, hyperchromic and megalocytic, and simple achlorhydric anæmia, hypochromic and microcytic.[1] One would expect to meet similar disturbances of the blood occasionally in carcinoma of the stomach. Thus when the gastric secretory defect entails the failure to form the intrinsic antianæmic factor (Castle) a megalocytic anæmia might appear which would respond for a time to the liver or stomach principle. Such cases have been reported by Simpson.[4] On the other hand, when chronic and persistent blood loss occurs in an individual on the border of iron starvation, the anæmia should be of the microcytic hypochromic type, and should respond for a time to large doses of iron. Anæmia of this type is an exact parallel to simple achlorhydric anæmia.[5] In such individuals other factors may play some part and, as in true simple achlorhydric anæmia, an initial poor reserve of iron may be due to a diet habitually poor in iron; but, be this as it may, iron starvation will certainly tend to develop in the presence of achlorhydria and pepsin defect (Mettier and Minot [6]).

Two practical points may be stressed from observations on these and other similar cases. The first relates to diagnosis: In any obscure case of anæmia of "secondary" microcytic hypochromic type it is *fallacious to believe that improvement in the blood* picture following the administration of iron is a point against the diagnosis of malignant disease. Providing there is no large hæmorrhage improvement may continue for a time in the face of secondary metastatic deposits.

The second point concerns the preparation of operable cases for gastrectomy. It is highly probable that the large majority of anæmic cases of carcinoma of the stomach can be improved by the administration of large doses of iron by mouth for a few weeks before operation. This improvement is enhanced by the simultaneous administration of hydrochloric acid and gastric lavage, which also facilitate the absorption of iron. To bring the blood condition up to what is desirable *for operation a transfusion may finally* be necessary, but the iron previously given has provided the patient with a reserve which will be available during convalescence, quite apart from the immediate contribution to the improvement in the anæmia.

In Case 3 there is a possibility that true uncomplicated simple achlorhydric anæmia was followed by the development of carcinoma of the stomach. The sex, the onset, and development of the anæmia, and the extremely dramatic response to iron, including the recession of the spleen favour this view. This would correspond to the cases recorded by Strandell,[7] Simpson [4] and Plummer,[8] of carcinoma developing in the stomachs of patients with Addisonian pernicious anæmia. According to Saltzman,[9] *if the association* is more than coincidence, and both the anæmia and neoplasm have a common basis of which the achlorhydria may be taken as an index, then such cases must occur with increasing frequency now that, without change in their gastric secretion, the lives of patients with pernicious anæmia are prolonged by treatment with liver.

SUMMARY

The changes in the gastric secretion associated with carcinoma of the stomach play an important part in the causation of the early anæmia sometimes met with in this disease.

The anæmia may be megalocytic and respond for a time to liver; this form is rare. It may be microcytic and temporarily respond to large doses of iron; this form is more common. Three such cases of microcytic anæmia, all of which responded to iron, are described in this paper.

I am indebted to Dr. A. F. Hurst for permission to investigate Cases 1 and 2, and to Dr. L. J. Witts for Case 3, and also for some details of the early history.

DIABETES MELLITUS AND INSIPIDUS

ASSOCIATED IN ONE CASE

By R. D. LAWRENCE, M.D. ABERD., F.R.C.P. LOND.
JUNIOR PHYSICIAN IN CHARGE OF THE DIABETIC DEPARTMENT, KING'S COLLEGE HOSPITAL
AND
R. A. McCANCE, M.D., PH.D. CAMB., M.R.C.P. LOND.
CHEMICAL PATHOLOGIST TO THE HOSPITAL

THE occurrence of diabetes mellitus and diabetes insipidus in the same patient is extremely rare. Although pathologically quite distinct, both diseases present the symptoms of thirst, polyuria, and wasting. When either disease is present alone, the glycosuria and high specific gravity in diabetes mellitus easily distinguishes it from diabetes insipidus, where the *urine contains no sugar and has a very low specific* gravity. But when both diseases are present, only modern methods of investigation, including blood-sugar estimations and a test of the effect of pituitary extract, can prove their coexistence.

No case which satisfies such criteria has been reported in this country. In America, however, F. N. Allan and L. G. Rowntree[1] have recently described two cases of their own (the only two in the Mayo Clinic since 1912) and have reviewed the existing literature. From this it appears that satisfactory proof of such cases is extremely rare.

The case now described demonstrates the combination of these two diseases in one patient, and shows their control by insulin and pituitary extract.

CASE RECORD

A man of 26 was first seen by Dr. R. Castello in April, 1931, when many symptoms suggesting *diabetes mellitus were present—lassitude, thirst,* polyuria, polyphagia. A heavy glycosuria was discovered and a half-hourly blood-sugar curve after 50 g. glucose gave the following results:—

Fasting	0·160 per cent.
½ hour after 50 g. glucose	0·210 „ „
1 „ „ „ „	0·270 „ „
1½ hrs. „ „ „	0·340 „ „
2 „ „ „ „	0·285 „ „

An 8-line (Lawrence) diet was instituted at first with small doses of insulin (5 b.d.). Later 13 lines and 10 and 8 units kept the patient aglycosuric and feeling well. In April, 1932, a succession of boils increased the insulin requirements to 14 and 12 units. This increased dosage soon produced severe hypoglycæmia for which the patient was admitted to the West London Hospital where the blood-sugar curve was repeated with the following results:—

Fasting	0·245 per cent.
1 hour after glucose	0·300 „ „
2 hours „ „	0·300 „ „

This further confirmed the diagnosis of diabetes mellitus and 10 units b.d. were recommended.

In July, 1932, the patient was seen by one of us in consultation and it was noticed that the urine contained only 0·4 per cent. of sugar, was pale like *water, and had a specific gravity of only 1003.* This was not consistent with the typical urinary findings in diabetes mellitus. Adjusting the diet and raising the insulin to 40 units per day adequately controlled *the diabetes mellitus, but did not appreciably* reduce the polyuria. The patient's measurements of the polyuria varied between 180 and 200 oz. per day

---

[1] Endocrinology, 1931, xv., 97.

(5300 c.cm.) and the specific gravity of the sugar-free urine remained between 1002–1004. Even when glycosuria was present, the specific gravity never rose above 1007. Diabetes insipidus was therefore suspected. A dose of pituitary extract (7·5 units= 0·75 c.cm.) was accordingly given at noon with the following results. The urine contained no sugar during the test.

Time.	Spec. grav.	Time.	Spec. grav.
Noon	1004	3 P.M.	1015
12·30 P.M.	1005	4 P.M.	1015
2 P.M.	1012		

The patient was admitted to King's College Hospital for fuller investigation, since the presence of both forms of diabetes seemed likely.

He was neuro- and psychosthenic, but showed no neurological abnormalities apart from sluggish tendon reflexes. No evidence of pituitary involvement was elicited; the optic discs and fields, and X ray examination of the fossa, were normal; the Wassermann test negative. No albumin or other abnormality *was present in the urine.*

The patient was not quantitatively resistant to insulin and required at his worst *only* 40 units a day on a diet of 80 g. carbohydrate, 75 protein, and 150 fat—quite a moderate dose. The insulin, however, acted unusually slowly and the blood-sugar was lowest, not 4 to 6 hours after insulin but much later, and hypoglycæmic symptoms appeared on several occasions 8 to 10 hours after insulin. He gained weight satisfactorily on adequate diabetic treatment, but continued to drink copiously and to pass 160–200 oz. of urine a day. When 5 units (0·5 c.cm.) pituitary extract were given morning and evening with the insulin this distressing thirst and polyuria disappeared:—

Days before pituitrin.	*Fluid* intake, oz.	Urine; volume.	*Days after* pituitrin.	Fluid intake, oz.	Urine; volume.
6	169	180	1	124	105
5	192	160			
4	175	138	2	108	80
3	180	190			
2	186	177	3	110	95
1	184	181			

These studies confirm the coexistence of idiopathic diabetes insipidus with true diabetes mellitus.

At first the insulin and the pituitary extract were given by separate injections, but later the two were measured and mixed in the same syringe and this was found to be equally effective. No more insulin was required when pituitrin was added to the insulin. It is fortunate that two such serious diseases can be controlled as easily as one in the same patient—though perhaps not so cheaply!

DISCUSSION

There is no evidence to suggest that the combination of these two diseases was other than fortuitous in this case. Nor did the patient's history give any clear idea of which disease occurred first, although he gave an indefinite history of a period of polyuria at the age of 8, 19 years previously.

We know that diabetes insipidus is due to a failure of pituitary function (hypofunction) and that a form of hyperpituitarism (acromegaly) may produce true diabetes mellitus. This patient, however, showed no stigmata suggesting previous acromegaly and therefore presents no evidence of any previous *pituitary lesion* which might account for the origin of the two diseases. In both of Allan and Rowntree's cases the diabetes insipidus preceded the appearance of the sugar by several years and the cause seemed to be a definitely dated pituitary lesion—a head injury in one and encephalitis in the other.

SUMMARY

1. A case is described in which diabetes mellitus and insipidus is present in the same patient. A combination seems fortuitous.

2. Treatment with insulin and pituitary extract controlled both diseases. No chemical or physiological antagonism was observed when the two hormones were mixed and injected together.

DERMATITIS FOLLOWING THE WEARING OF DYED FABRICS

By E. M. Killick, M.B., B.Sc. Leeds,
M.R.C.P. Lond.
RESEARCH ASSISTANT, DEPARTMENT OF PHYSIOLOGY,
UNIVERSITY OF LEEDS

AND

John T. Ingram, M.D., M.R.C.P. Lond.
PHYSICIAN IN CHARGE OF THE DERMATOLOGICAL DEPARTMENT,
GENERAL INFIRMARY, LEEDS; LECTURER ON DISEASES
OF THE SKIN IN THE UNIVERSITY

The report of Parsons (1927) to the Ministry of Health drew attention to dermatitis resulting from the wearing of dyed furs, and suggested, from the evidence, that the condition was of the nature of a personal idiosyncrasy and occurred in people not ordinarily disposed to dermatitis. The subject has received much attention, and the general consensus of *opinion holds that the* reaction is due to the use of amines, diamines, aminophenols, diphenols, and their substitutes in the dyeing of furs. It is suggested, from the work of Gordon (1924–26), that the irritant present in dyed furs is an oxidation product of para-phenylenediamine. A recent paper by Percival (1931) is of considerable interest. Percival shows first that, of the several chemical substances employed in the preparation of the fur, only one, substance A (which is known to contain para-phenylenediamine), and the oxidation product of substance A, is the factor which takes any part in the production of dermatitis; secondly, that the dermatitis depends on an allergic state of the skin, and that it is idiosyncratic in nature.

Chemical analysis can, in view of these findings, yield no evidence of the biological effect of a dyed material. The correct use of the so-called "patch test" is therefore of importance. Bloch (1924–29) has used this method to demonstrate the idiosyncrasy of individuals to poison ivy, primula leaves, orthoform, &c. Sulzberger and Wise (1923) give a full description of the contact or patch test in dermatology, and, according to these authors, investigation by the test is applicable to such conditions as acute occupational dermatitis, dermatitis venenata, dermatitis medicamentosa, and drug eruptions of eczematous type (Ingram (1932)).

RECORDED CASES

While the diagnosis of fur dermatitis has become established, skin reactions due to dyes or to the wearing of dyed material other than furs have been almost unrecognised, and little information is available in the literature. Sezary, Lefevre, and Rivoire *(1930)* have described one case of artificial dermatitis of the neck after contact with a parti-coloured red and yellow *dyed silk handkerchief*; the inflammation was localised to the area of the skin in direct contact with the material. A yellow colouring matter, azofluvine, was extracted from the yellow coloured material, and azarine S from the red area.

anæmia.[5] In such individuals other factors may play some part and, as in true simple achlorhydric anæmia, an initial poor reserve of iron may be due to a diet habitually poor in iron; but, be this as it may, iron starvation will certainly tend to develop in the presence of achlorhydria and pepsin defect (Mettier and Minot [6]).

Two practical points may be stressed from observations on these and other similar cases. The first relates to diagnosis: In any obscure case of anæmia of "secondary" microcytic hypochromic type it is fallacious to believe that improvement in the blood picture following the administration of iron is a point against the diagnosis of malignant disease. Providing there is no large hæmorrhage improvement may continue for a time in the face of secondary metastatic deposits.

The second point concerns the preparation of operable cases for gastrectomy. It is highly probable that the large majority of anæmic cases of carcinoma of the stomach can be improved by the administration of large doses of iron by mouth for a few weeks before operation. This improvement is enhanced by the simultaneous administration of hydrochloric acid and gastri clavage, which also facilitate the absorption of iron. To bring the blood condition up to what is desirable for operation a transfusion may finally be necessary, but the iron previously given has provided the patient with a reserve which will be available during convalescence, quite apart from the immediate contribution to the improvement in the anæmia.

In Case 3 there is a possibility that true uncomplicated simple achlorhydric anæmia was followed by the development of carcinoma of the stomach. The sex, the onset, and development of the anæmia, and the extremely dramatic response to iron, including the recession of the spleen favour this view. This would correspond to the cases recorded by Strandell,[7] Simpson [4] and Plummer,[8] of carcinoma developing in the stomachs of patients with Addisonian pernicious anæmia. According to Saltzman,[9] if the association is more than coincidence, and both the anæmia and neoplasm have a common basis of which the achlorhydria may be taken as an index, then such cases must occur with increasing frequency now that, without change in their gastric secretion, the lives of patients with pernicious anæmia are prolonged by treatment with liver.

SUMMARY

The changes in the gastric secretion associated with carcinoma of the stomach play an important part in the causation of the early anæmia sometimes met with in this disease.

The anæmia may be megalocytic and respond for a time to liver; this form is rare. It may be microcytic and temporarily respond to large doses of iron; this form is more common. Three such cases of microcytic anæmia, all of which responded to iron, are described in this paper.

I am indebted to Dr. A. F. Hurst for permission to investigate Cases 1 and 2, and to Dr. L. J. Witts for Case 3, and also for some details of the early history.

DIABETES MELLITUS AND INSIPIDUS

ASSOCIATED IN ONE CASE

BY R. D. LAWRENCE, M.D. ABERD., F.R.C.P. LOND.
JUNIOR PHYSICIAN IN CHARGE OF THE DIABETIC DEPARTMENT, KING'S COLLEGE HOSPITAL
AND
R. A. MCCANCE, M.D., PH.D. CAMB., M.R.C.P. LOND.
CHEMICAL PATHOLOGIST TO THE HOSPITAL

THE occurrence of diabetes mellitus and diabetes insipidus in the same patient is extremely rare. Although pathologically quite distinct, both diseases present the symptoms of thirst, polyuria, and wasting. When either disease is present alone, the glycosuria and high specific gravity in diabetes mellitus easily distinguishes it from diabetes insipidus, where the urine contains no sugar and has a very low specific gravity. But when both diseases are present, only modern methods of investigation, including blood-sugar estimations and a test of the effect of pituitary extract, can prove their coexistence.

No case which satisfies such criteria has been reported in this country. In America, however, F. N. Allan and L. G. Rowntree [1] have recently described two cases of their own (the only two in the Mayo Clinic since 1912) and have reviewed the existing literature. From this it appears that satisfactory proof of such cases is extremely rare.

The case now described demonstrates the combination of these two diseases in one patient, and shows their control by insulin and pituitary extract.

CASE RECORD

A man of 26 was first seen by Dr. R. Castello in April, 1931, when many symptoms suggesting diabetes mellitus were present—lassitude, thirst, polyuria, polyphagia. A heavy glycosuria was discovered and a half-hourly blood-sugar curve after 50 g. glucose gave the following results:—

Fasting	0·160 per cent.
½ hour after 50 g. glucose.. ..	0·210 ,, ,,
1 ,, ,, ,, ,, ...	0·270 ,, ,,
1½ hrs. ,, ,, ,, ...	0·340 ,, ,,
2 ,, ,, ,, ,, ...	0·285 ,, ,,

An 8-line (Lawrence) diet was instituted at first with small doses of insulin (5 b.d.). Later 13 lines and 10 and 8 units kept the patient aglycosuric and feeling well. In April, 1932, a succession of boils increased the insulin requirements to 14 and 12 units. This increased dosage soon produced severe hypoglycæmia for which the patient was admitted to the West London Hospital where the blood-sugar curve was repeated with the following results:—

Fasting	0·245 per cent.
1 hour after glucose	0·300 ,, ,,
2 hours ,, ,, ...	0·300 ,, ,,

This further confirmed the diagnosis of diabetes mellitus and 10 units b.d. were recommended.

In July, 1932, the patient was seen by one of us in consultation and it was noticed that the urine contained only 0·4 per cent. of sugar, was pale like water, and had a specific gravity of only 1003. This was not consistent with the typical urinary findings in diabetes mellitus. Adjusting the diet and raising the insulin to 40 units per day adequately controlled the diabetes mellitus, but did not appreciably reduce the polyuria. The patient's measurements of the polyuria varied between 180 and 200 oz. per day

---

[1] Endocrinology, 1931, xv., 97.

(5500 c.cm.) and the specific gravity of the sugar-free urine remained between 1002–1004. Even when glycosuria was present, the specific gravity never rose above 1007. Diabetes insipidus was therefore suspected. A dose of pituitary extract (7·5 units = 0·75 c.cm.) was accordingly given at noon with the following results. The urine contained no sugar during the test.

Time.	Spec. grav.	Time.	Spec. grav.
Noon	1004	3 P.M.	1015
12·30 P.M.	1005	4 P.M.	1015
2 P.M.	1012		

The patient was admitted to King's College Hospital for fuller investigation, since the presence of both forms of diabetes seemed likely.

He was neuro- and psychosthenic, but showed no neurological abnormalities apart from sluggish tendon reflexes. No evidence of pituitary involvement was elicited; the optic discs and fields, and X ray examination of the fossa, were normal; the Wassermann test negative. No albumin or other abnormality was present in the urine.

The patient was not quantitatively resistant to insulin and required at his worst only 40 units a day on a diet of 80 g. carbohydrate, 75 protein, and 150 fat—quite a moderate dose. The insulin, however, acted unusually slowly and the blood-sugar was lowest, not 4 to 6 hours after insulin but much later, and hypoglycæmic symptoms appeared on several occasions 8 to 10 hours after insulin. He gained weight satisfactorily on adequate diabetic treatment, but continued to drink copiously and to pass 160–200 oz. of urine a day. When 5 units (0·5 c.cm.) pituitary extract were given morning and evening with the insulin this distressing thirst and polyuria disappeared:—

Days *before* pituitrin.	Fluid intake, oz.	Urine; volume.	Days *after* pituitrin.	Fluid intake, oz.	Urine; volume.
6	169	180	1	124	105
5	192	160			
4	175	138	2	108	80
3	180	190			
2	186	177	3	110	95
1	184	181			

These studies confirm the coexistence of idiopathic diabetes insipidus with true diabetes mellitus.

At first the insulin and the pituitary extract were given by separate injections, but later the two were measured and mixed in the same syringe and this was found to be equally effective. No more insulin was required when pituitrin was added to the insulin. It is fortunate that two such serious diseases can be controlled as easily as one in the same patient—though perhaps not so cheaply!

DISCUSSION

There is no evidence to suggest that the combination of these two diseases was other than fortuitous in this case. Nor did the patient's history give any clear idea of which disease occurred first, although he gave an indefinite history of a period of polyuria at the age of 8, 19 years previously.

We know that diabetes insipidus is due to a failure of pituitary function (hypofunction) and that a form of hyperpituitarism (acromegaly) may produce true diabetes mellitus. This patient, however, showed no stigmata suggesting previous acromegaly and therefore presents no evidence of any previous pituitary lesion which might account for the origin of the two diseases. In both of Allan and Rowntree's cases the diabetes insipidus preceded the appearance of the sugar by several years and the cause seemed to be a definitely dated pituitary lesion—a head injury in one and encephalitis in the other.

SUMMARY

1. A case is described in which diabetes mellitus and insipidus is present in the same patient. A combination seems fortuitous.

2. Treatment with insulin and pituitary extract controlled both diseases. No chemical or physiological antagonism was observed when the two hormones were mixed and injected together.

DERMATITIS FOLLOWING THE WEARING OF DYED FABRICS

By E. M. Killick, M.B., B.Sc. Leeds, M.R.C.P. Lond.
RESEARCH ASSISTANT, DEPARTMENT OF PHYSIOLOGY, UNIVERSITY OF LEEDS

AND

John T. Ingram, M.D., M.R.C.P. Lond.
PHYSICIAN IN CHARGE OF THE DERMATOLOGICAL DEPARTMENT, GENERAL INFIRMARY, LEEDS; LECTURER ON DISEASES OF THE SKIN IN THE UNIVERSITY

THE report of Parsons (1927) to the Ministry of Health drew attention to dermatitis resulting from the wearing of dyed furs, and suggested, from the evidence, that the condition was of the nature of a personal idiosyncrasy and occurred in people not ordinarily disposed to dermatitis. The subject has received much attention, and the general consensus of opinion holds that the reaction is due to the use of amines, diamines, aminophenols, diphenols, and their substitutes in the dyeing of furs. It is suggested, from the work of Gordon (1924–26), that the irritant present in dyed furs is an oxidation product of para-phenylenediamine. A recent paper by Percival (1931) is of considerable interest. Percival shows first that, of the several chemical substances employed in the preparation of the fur, only one, substance A (which is known to contain para-phenylenediamine), and the oxidation product of substance A, is the factor which takes any part in the production of dermatitis; secondly, that the dermatitis depends on an allergic state of the skin, and that it is idiosyncratic in nature.

Chemical analysis can, in view of these findings, yield no evidence of the biological effect of a dyed material. The correct use of the so-called "patch test" is therefore of importance. Bloch (1924–29) has used this method to demonstrate the idiosyncrasy of individuals to poison ivy, primula leaves, orthoform, &c. Sulzberger and Wise (1923) give a full description of the contact or patch test in dermatology, and, according to these authors, investigation by the test is applicable to such conditions as acute occupational dermatitis, dermatitis venenata, dermatitis medicamentosa, and drug eruptions of eczematous type (Ingram (1932)).

RECORDED CASES

While the diagnosis of fur dermatitis has become established, skin reactions due to dyes or to the wearing of dyed material other than furs have been almost unrecognised, and little information is available in the literature. Sezary, Lefevre, and Rivoire (1930) have described one case of artificial dermatitis of the neck after contact with a parti-coloured red and yellow dyed silk handkerchief; the inflammation was localised to the area of the skin in direct contact with the material. A yellow colouring matter, azofluvine, was extracted from the yellow coloured material, and azarine S from the red area.

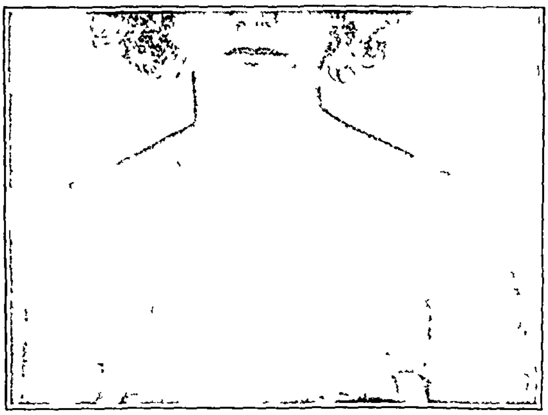
White (1897) described five cases of dermatitis following the wearing of unwashed black cotton shirts. Symptoms appeared in each case about ten days after the shirts were first worn; the lesion was sharply confined to those areas of the skin in contact with the shirt and consisted of an infiltrated erythema. The shirts were dyed with aniline black. Porosz (1924) reported two cases of localised dermatitis of the legs following the wearing of black socks. The dye concerned was again aniline black, and the lesion produced was similar to that described by White.

In our opinion, dermatitis due to common dyes is more frequent than is usually supposed. The reaction is not dependent on the presence of any abnormal substance, but results from the contact of the skin with the dye, which, though harmless to the majority of individuals, causes dermatitis in some subjects. The idiosyncratic nature of the reaction can be definitely established on investigation, and we have recently seen an individual who reacted to a dye previously considered harmless. In this paper this case is reported in full, since it serves as an excellent example of the class, and, further, we were able to examine the patient and carry out part of our investigations during the very acute stage of the illness.

HISTORY OF A CASE

On August 29th, 1931, Mrs. X., aged 35 years, consulted one of us for a dermatitis affecting the upper part of her trunk, which was so irritable that it caused loss of sleep and impaired her general health. She attributed her condition to the wearing of a blouse which had recently been sent to a garment dyer to be dyed black.

FIG. 1



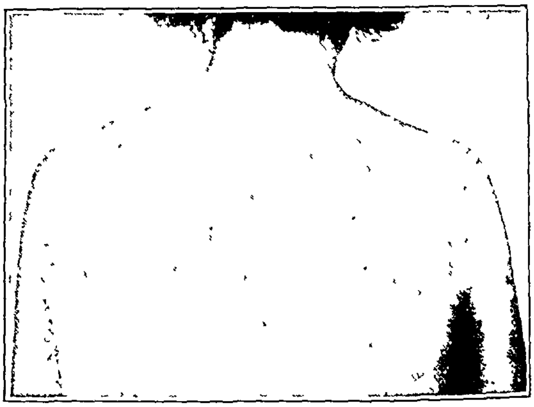
Photograph of eruption affecting upper chest and shoulders but not involving skin protected by shoulder-straps and petticoat.

The fabric of the blouse was a mixture of cotton and a regenerated cellulose artificial silk, and was originally pink in colour. On July 25th the blouse was sent to a firm of dyers and was returned after a few days dyed black as ordered. The garment was first worn about a week later, on August 2nd or 3rd.

The blouse was worn for about 14 days without serious inconvenience. After a few days' wear the skin of the folds of the axillæ and the flexor surfaces of the forearms was observed to be stained with dye; later, the skin became irritable and a rash appeared. About August 16th the patient stopped wearing the blouse, as she and her doctor suspected it of being the probable cause of the skin condition. Although the blouse was not worn again, the eruption increased in severity during the period August 16th to 29th, when she was first examined by one of us.

On examination the rash was found to have a striking distribution limited to the upper part of the trunk, being strictly confined to those areas of the upper thorax and shoulders left uncovered by the patient's undergarments. The rash was limited in front to about the level of the third rib, spreading over the shoulders and slightly on to the neck, avoiding only the skin protected by the shoulder-straps, and a V-shaped area corresponding to the front of the blouse. It extended down the back to about the same level as on the front of the chest. The hollows of the axillæ were clear and the eruption faded on the upper arms, but reappeared over the flexor aspects of the elbows. The lesion was an acute, œdematous, uniform, papular, eczematous eruption, and was intensely irritable. The unique distribution and character of the dermatitis made it obvious that it arose from some form of external irritant (Figs. 1 and 2).

FIG. 2



Photograph of eruption affecting upper back and shoulders but not involving skin protected by shoulder-straps and petticoat.

No ætiological factors other than the wearing of the dyed garment could be elicited from the patient's history. Apart from three small patches of chronic psoriasis of the scalp, from which the patient had suffered for 12 years, there was no sign or history of skin disease. No family history of asthma, urticaria, or eczema could be obtained.

The patient had taken a small quantity of thyroid daily for ten days during July, but had ceased this treatment for a month prior to consulting us. After the appearance of the skin eruption, antipyrin was prescribed to relieve the itching and to promote sleep. Local application of "Germolene," lead lotion, calamine lotion, "Resinol ointment" had all been tried prior to August 29th to relieve the skin affection.

The patient had not used hair dyes or depilatories, and no chemicals had been applied to the skin until after the onset of the rash. No new garments other than the dyed blouse had been worn which could account for the onset of the trouble. She gave no history of previous eruptions from dyed materials.

Clinical examination failed to reveal any constitutional or organic abnormalities and no disorders of function were detected. Special examinations carried out included urine analyses, blood-sugar and blood-urea estimations, blood-sugar curves following the ingestion of glucose, and the blood Wassermann reaction. The Wassermann reaction was negative, and the results of the other examinations were found to be well within normal limits.

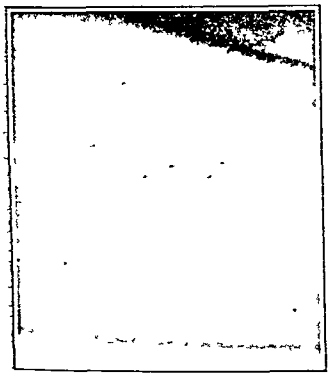
"PATCH TEST" INVESTIGATION

On Monday, August 31st, a "patch test" was made. A portion of the blouse, approximately 2 in. square, was placed on the flexor aspect of the right wrist, covered with lint, which was again covered with a square of gutta-percha tissue and strapped on the forearm. A piece of lint without a portion of the blouse was applied in a similar manner, as a control, to the flexor aspect of the left forearm. The applications were removed 40 hours later. The skin of the left forearm was normal, while that of the right forearm presented an area of acutely irritable, œdematous erythema, raised about one-eighth of an inch above the surface level of the skin, and localised to an area exactly corresponding to the position of the dyed material. The lint covering the piece of dyed material was observed to be well stained with dye. The patient stated that the right forearm became irritable some 24 hours after the application of the material. The area was still acutely inflamed five days later. Treatment was then applied and the condition subsided, though it was still possible to recognise the area on Sept. 12th.

Three control tests were made at the same time on healthy persons. Similar applications were made, as described above, to the flexor surfaces of the forearm of one female and two male adults. The results were negative after contact for 40 hours: the skin and the lint were observed in each case to be stained with dye.

A weak cold water extract obtained from the material was next applied to the skin of the patient's forearm. The extract was reapplied after 6 hours and again after 18 hours. The patient stated that the site became red and irritable two days later. The reaction disappeared in 24 to 48 hours.

FIG. 3



Patch test reaction. A portion of the blouse, disc-shaped, with centre cut out, was applied to left forearm for 24 hours, seven months after the original attack of dermatitis had subsided. The photograph shows the reaction.

The fastness of the dyed material to perspiration was then examined.

Artificial perspiration liquors were used which had been previously shown to have the same action as perspiration on dyed artificial silk. Vass and McSwiney (1930) demonstrated that perspiration undergoes considerable changes on standing; there is a marked increase in the ammonia nitrogen content with a disappearance of urea nitrogen, the reaction becoming definitely alkaline, due to bacteria normally associated with freshly shed perspiration. Acid and alkaline solutions were therefore used, of the following composition:—

Acid solution.—2·65 g. common salt and 0·75 g. urea per litre, brought to pH 5·6 with normal acetic acid.

Alkaline solution.—0·839 g. ammonium chloride, 1·732 g. common salt, and 0·424 c.cm. ammonia (spec. grav. 0·88) per litre, brought to pH 7·8 with normal acetic acid.

The material was backed between pieces of neutral undyed wool and white cotton, then thoroughly wetted in the acid or alkaline solution. The fabrics were passed through rollers to give 100 per cent. increase in dry weight. The damped materials were wrapped round a chemically cleaned glass tube and inserted into a second glass tube, so that equal pressure might be exerted over the whole area of the pattern. After incubation at 37° C. for two hours the materials were allowed to dry and then examined. The wool and cotton backings were found to be deeply stained, demonstrating that the dye bled readily from the fabric both in acid and alkaline perspiration liquors.

To establish whether the dyed material would act as an irritant to the normal person, the response of a large number of individuals to the fabric was investigated, using the patch test.

A portion of the material, approximately 2 in. by 1 in., was placed on the back or arm, covered with a square of gutta-percha, and strapped to the skin (B.1). Pieces of green (G), red (R), and two black materials (B.2 and B.3), were applied at the same time. These materials were stated to have provoked dermatitis in other individuals. The fabrics were allowed to remain in contact with the skin for 24 hours, when the strapping was removed and the skin examined. The response was stated to be positive if a rash was visible in the area covered by the fabric for a period of at least 12 hours. The investigation was extended to individuals suffering from various forms of skin and other diseases. The patch test was again employed as in the previous experiments, the fabric being placed in contact with an area of normal skin.

Results of Patch Tests with Dyed Fabrics, B.1, G, R, B.2, B.3

Normal subjects.	Sex.	Reaction.
30	Male.	Negative.
6	Female.	,,

The skin conditions included lupus vulgaris, lupus erythematosus, urticaria, seborrhœic and eczematous dermatitis.

Subjects of skin diseases.	Sex.	Reaction.
31	Female.	Negative.
38	Male.	,,

It will be seen from the Table that only negative results were obtained from normal subjects and from individuals suffering from skin and other diseases, with the exception of Mrs. X., who demonstrated a marked reaction. This subject was so sensitive that she reacted to a dilute watery extract of the dyed material. She failed to react to the other dyed fabrics, G, R, B.2, and B.3. The idiosyncrasy could therefore be said to be specific. A patch test performed seven months later (March 15th, 1932) against the dyed fabric B.1—using two further control materials—again provoked an acute positive reaction (Fig. 3). This reaction, however, did not appear until 48 hours after removal of the test. It is interesting to note that the idiosyncrasy appears to be lasting, and that the latent period of the reaction is increased.

Dr. F. M. Rowe, professor of colour chemistry in the University of Leeds, was consulted as to the treatment the material in question had received. At his suggestion a piece of the material was submitted to him for examination, and we wish to express our thanks to him for the following report:—

Examination of the black blouse.—The material is a thin fabric consisting of a cotton warp and a viscose artificial silk weft, such as is commonly used for making blouses or dresses. It was dyed solely with azo direct (substantive) dyes—i.e., the pink dye with which the blouse was dyed originally and the black dye used by the garment dyer both belonged to the class of azo direct dyes. It is not possible to name the actual black dye, but it is clearly of a type manufactured for many years by most firms of dye-makers throughout the world for use extensively for dyeing a variety of textile materials, as well as in garment dyeing. It is a dye which has always been regarded as suitable for use in garment dyeing, and it is clear that the blouse had been dyed in the usual and proper manner. A dye of this kind is only moderately fast, and by steeping a portion of the blouse in water or dilute ammonia, or by prolonged steeping in dilute acetic acid at body heat, coloured solutions were obtained.

Taking the properties of azo direct dyes into consideration, extracts were prepared which would have contained any undesirable organic compound, if such had been present in the blouse. The extracts were submitted to a range of definite and characteristic tests, which undoubtedly would have demonstrated the presence of any compounds, such as meta- or para-diamines, para-amino-phenols, &c. There was not the slightest indication of the presence of any of these organic compounds in the extracts, whereas control tests carried out simultaneously were strongly positive in every case.

It has been suggested that substances such as para-phenylene-diamine, para-aminophenol, are sometimes present in dyed materials (O'Donovan, 1930). McCafferty (1926) states that "many furs, stockings, and dress goods are dyed with para-phenylene-diamine." In Prof. Rowe's opinion, this statement is true as far as dyed furs are concerned, although even in this case the original para-phenylene-diamine or para-aminophenol used in dyeing should not be present in the finished fur if the subsequent washing has been efficient. It is not true of ordinary textile materials consisting of artificial silks, cotton, natural silk, wool, &c., as they are never dyed by using compounds of the type quoted.

There apparently exists a belief that dermatitis arising from the wearing of a dyed material is caused by some compound such as para-phenylene-diamine, with which the dyes employed are contaminated. In our opinion, this is not true, and we have therefore reported this case in some detail, as we have recently been in touch with cases of dermatitis due to the wearing of materials dyed with normal types of textile dyes. We believe this condition to be more common than the lack of information would suggest.

PROGRESSIVE POST-OPERATIVE GANGRENE OF THE SKIN

BY F. HECTOR SCOTSON, M.B. LOND., F.R.C.S. ENG.

HONORARY SURGEON, MANCHESTER VICTORIA MEMORIAL JEWISH HOSPITAL; HONORARY ASSISTANT SURGEON, MANCHESTER NORTHERN HOSPITAL

THIS interesting and apparently rare condition has received little or no attention in the British text-books and surgical literature, although several cases appear from American sources.

In the reported cases it has almost always occurred within a week or two of operation with drainage for acute appendicitis. The process generally starts in part of the wound, or in a stitch hole, as an indurated red area, tender and intensely painful, which advances with temporary remissions and exacerbations. The fully developed gangrenous process appears as a central black leathery slough surrounded by an indurated, red, inflammatory zone, and underlying this is a yellowish, infiltrated area where pus formation is at a minimum. The deeper structures are not affected, the skin and subcutaneous tissue alone being involved. A moderate rise in temperature—to 102° F. —accompanies the gangrene, although the patient does not seem to suffer so much from a severe toxæmia as from continued exhaustion and lack of sleep due to the severe pain.

In most of the recorded cases the accompanying organisms appear to be a combination of non-hæmolytic streptococci and staphylococci. In none of the cases, however, does there appear to be any underlying disease, such as syphilis or diabetes, as a causative agent.

The only treatment of any avail is excision of the entire inflamed and necrotic area, well clear of the area of infiltration, with the diathermy cautery. No other local measure has any influence on the process, which proceeds in an ever-enlarging area till its advance is checked by the above means.

CASE REPORT

A male, aged 62, was seen by me on August 15th, 1931. He gave a history of pain in the right lower abdomen for the past week which had not been severe until August 14th; he had not vomited. Examination revealed a mass about the size of a golf-ball in the right iliac fossa; there was marked tenderness. The diagnosis of acute appendicitis with abscess was made, and operation was carried out under general anæsthesia.

A rectus slide incision was made and a localised mass was found. This was packed off with gauze and an opening made into it. The appendix was found in the mass, swollen, perforated, and gangrenous, with an abscess containing two or three ounces of foul-smelling pus surrounding it. The pus was mopped up and the appendix removed, and the abdomen was closed with a rubber tube drain to the abscess site.

A small amount of pus was discharged from the tube track, and as this rapidly decreased the tube was removed on the sixth day. The remainder of the wound healed without any appreciable amount of suppuration, and for the first ten days following the operation the patient made good progress.

On the tenth day a small red patch of inflammation made its appearance in the upper part of the abdominal incision—i.e., distal to the site of the drainage-tube. This patch at first had all the appearances of an abscess in the abdominal wall and, except for the extreme pain which it occasioned, seemed to be of no great moment.

The area of inflammation continued to spread, and by Sept. 16th was about three inches in diameter with a central black slough and a surrounding red inflammatory zone. On this date the black necrotic area was excised with a scalpel under nitrous oxide anæsthesia, and eusol dressings were applied. There was a brief temporary improvement in the local and general condition of the patient, and the pain was distinctly easier. Soon, however, the inflammatory process continued to advance and, after a short trial of more energetic local treatment—viz., the application of a paste of dried magnesium sulphate and glycerin, combined with the application of artificial sunlight and continuous heat from an electric pad to the wound—further operative treatment was decided upon. Incisions, again under nitrous oxide anæsthesia, were made undercutting the gangrenous flaps and extending into healthy tissue, and a similar local treatment was used. Again there was a temporary improvement. So far, ever since the appearance of the gangrene, the patient's temperature had varied from normal to 102° F., and his general condition, in spite of the severe pain, remained satisfactory.

Despite all treatment, local and general, the gangrenous process continued to advance. In addition to the treatments already mentioned the following were tried without success.

Ichthyol 30 per cent. and iodine solution was used as a local application together with large doses of *potassium iodide* internally, owing to a resemblance between the appearance of the wound and a blastomycosis infection of the skin. *Diphtheria antitoxin* in large doses was given later, as occasionally a true diphtheritic inflammation has been observed in abdominal wounds following operation, and somewhat resembling the process in question. This serum seemed to produce a definite improvement which was, however, short-lived. Other remedies used without avail were *manganese butyrate* and *Edwenil* intramuscularly, and *staphylococcal antivirus* locally.

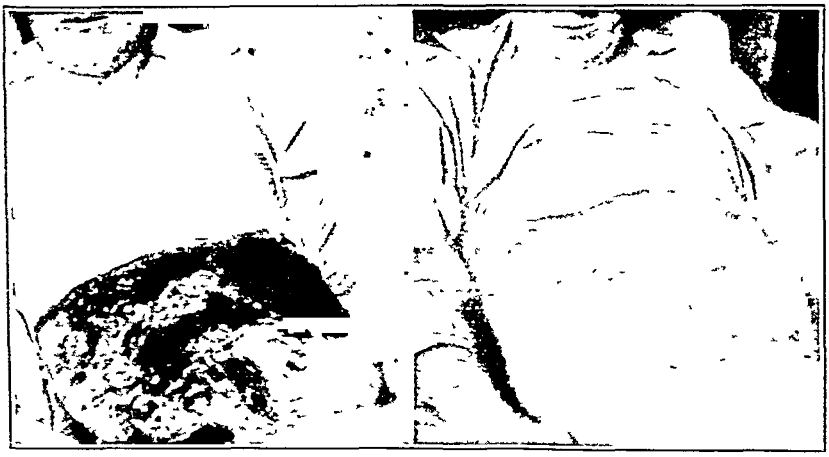
In about two months from the date of the operation the wound extended superiorly to within 2 inches of the costal margin, inferiorly to within an inch or two of Poupart's ligament, to the right to the anterior axillary line, and to the left above the level of the operation wound to the mammary line on this side. It was noticed that the gangrene did not extend into or across the operation scar, and so the area directly to the left of this was healthy.

The bacteriological report (Oct. 20th) showed that on culture the predominant organism was a streptococcus. There were also a number of colonies of hæmoglobinophil Gram-negative bacilli which were influenza bacilli, and a few colonies of staphylococci.

By this time the condition appeared so hopeless that treatment to be of any avail had obviously to be of a heroic nature. The fact that the gangrenous process stopped at the line of the abdominal scar suggested that it would be rational to cut a trench well clear of the inflammatory area through the skin into the subcutaneous tissue so that when the inflammation reached to this level a barrier of scar tissue would have formed and so arrest further progress.

Accordingly on Oct. 22nd a trench was cut and a few sloughs were excised with the diathermy cautery. As the gangrene advanced the process was arrested at this line, transgressing it only on the left side and slightly in one small area to the right, and accordingly the diathermy was again used in a similar manner on Nov. 10th. This effectually stopped any further spread, and finally on Nov. 21st, again with a general anæsthetic, the partially separated sloughs were excised so as to hasten the appearance of repair tissue. After this the wound appeared as a clean area upon which skin might be expected to grow from the wound margins. It is interesting to note that an area of skin to the right side, around which we cut the trench, failed to slough and so helped in the repair of the very large wound.

At first eusol was used to dress the wound, and later the whole area was covered with broad strips of elastic plaster bandage which were renewed about every ten days, the discharge from the surface easily permeating the bandage and being washed off with cold water and soap. Up to a point this proved a very satisfactory dressing, and the wound showed rapid healing, but for the final stages of repair a boric acid ointment dressing seemed to be the better application.



The left-hand photograph shows the wound after the second diathermy operation but before the excision of the sloughs; the one on the right shows it as it finally healed.

Two important complications occurred during the stage of healing. Firstly a pneumonia of the right lung developed: this was probably of embolic origin, the patient early expectorating blood. This pneumonia gave rise to a great deal of anxiety, the patient being delirious for about ten days and his general condition far from good. About a fortnight or so after this had cleared up satisfactorily the patient commenced a well-marked "white leg" which necessitated a further six weeks' rest in bed, but which settled satisfactorily.

It had been our intention to skin-graft the large wound after the final diathermy on Nov. 21st, but this operation was delayed by the complications, and as time went on the skin advanced in a most satisfactory manner from the edges of the wound and from islets of epithelium in the base which must have escaped the gangrenous process.

OTHER RECORDS

The following is a brief summary of similar cases of which I have found records.

Cullen[1] reports a case occurring after an appendicectomy with drainage. The gangrenous process was eradicated only after the actively growing edge of the ulcer was excised with the cautery. The organism in his case was a *Streptococcus brevis*.

Christopher's[2] case followed a rib resection for empyema, and the organisms found were a Gram-positive coccus and a Gram-negative bacillus.

In Brewer and Meleny's[3] case, following operation for acute perforated appendix, a streptococcus and a staphylococcus were isolated from the ulcer and these, when injected beneath the skin of animals, produced a gangrenous slough. These authors suggest as an ætiological factor a symbiosis of these organisms, as either separately failed to produce any ulceration.

Shipley[4] has reported a progressive gangrenous ulceration of the abdominal wall following the drainage of an appendix abscess, and in this case a non-hæmolytic streptococcus was isolated. In a similar case reported by Mayeda[5] an organism resembling the diphtheria bacillus was found.

In Cole and Heideman's[6] case a progressive ulcer of the abdominal wall started in a stitch hole 18 days after an operation with drainage for appendicitis. The main interest of this case is the fact that an amœbic organism was found in the pus and edge of the ulcer and, owing to the similarity with the other reported cases, they suggest an amœba rather than a bacterium as the cause of this condition. It is to be noted that their patient had not suffered from dysentery and that, although emetine led to some improvement, the condition only responded satisfactorily to cautery excision.

Freeman[7] gives an account of this interesting complication 12 days after an operation for gall-stones, the origin being from a stitch hole. The necrotic area in this case was never excised, as a nephritis developed and caused the man's death in less than two months from the date of the operation. He states that the microbic cause could not be determined, there being a confusing multitude of micro-organisms. He quotes Tennant's case which developed the condition following operation for ventral hernia and in which the disease was arrested by the use of artificial and direct sunlight.

Smith[8] mentions a case of progressive ulceration of the abdominal wall following appendicectomy, but in this case the Klebs-Löffler bacillus was isolated and the process yielded in the ordinary way to large doses of antitoxin. This is obviously quite a different form of ulceration from the one in question, and is only mentioned as in our case large doses of antitoxin were empirically tried with apparently some temporary success, although no diphtheria bacilli were found.

Baker and Terry[9] give an account of a case where the gangrene followed nine days after operation with drainage for acute appendicitis, and the process was finally arrested only after excision with the electro-cautery.

SUMMARY

A type of wound infection is described which leads to progressive gangrenous ulceration of the skin. The process is most common after operation with drainage for appendicitis and starts as a rule between one and two weeks after the operation, either in a stitch hole or the wound. The affected skin is first red, then finally gangrenous, and the area is intensely painful and tender. The organism most commonly found is a streptococcus, but in at least three of the above cases there has been found in addition a staphylococcus, lending support to the theory of Brewer and Meleny that the ætiology of the condition may be a symbiosis of these two organisms. The only effective treatment is excision of the area by the cautery or diathermy knife.

I am much indebted to Mr. Wilson Hey and Dr. William Dyson for their valuable suggestions regarding the final treatment adopted; to Dr. G. E. Loveday for the bacteriological examination; and to Dr. C. A. Travers for his constant help and coöperation.

Clinical and Laboratory Notes

PATENT DUCTUS ARTERIOSUS
WITH INFECTIVE ENDOCARDITIS

By James W. Brown, M.D., M.R.C.P. Lond.
PHYSICIAN TO THE GRIMSBY AND DISTRICT HOSPITAL

The association of infective endocarditis with congenital heart disease and with patency of the ductus arteriosus has been emphasised by Hamilton and Abbott,[1] Bedford and Boldero,[2] Horder.[3] Libman,[4] Maud Abbott,[5] and others. The following is a brief account of a case in which a patent ductus arteriosus was complicated by an infective endocarditis.

A schoolboy, aged 12, was first seen in 1929 with reference to his heart. When he had measles at the age of 8 he had an accompanying severe bronchitis with cyanosis. Examination of his chest at that time led to the discovery of a hitherto unsuspected cardiac lesion. He had never been a robust child, and was so susceptible to respiratory infections that his attendance at school had only been fitful.

On examination he was found to be undersized for his age, but mentally up to standard. There was no evidence of any external physical defect. Cyanosis and clubbing of the fingers were absent. The pulse was regular and the temperature normal. The tonsils were large and ragged. Pulsation was visible in the second and third left interspaces close to the sternum. The apex-beat was in the fifth space 3¼ inches from the mid-sternal line. A systolic thrill was best felt in the second left intercostal space. Gerhardt's ribbon dullness was not detected. On auscultation a bruit of the continuous or machinery type was present and was best heard close to the sternum in the second left interspace. The pulmonary second sound was reduplicated. The spleen could not be felt. Pulsation was present in the abdominal aorta and femoral vessels. Radiological examination showed that the heart was enlarged to the right and left. There was a prominent bulge on the left middle arc of the cardiac silhouette, which vigorously pulsated. A diagnosis of patent ductus arteriosus was made.

Final illness.—In June, 1930, six months after the previous examination, he was admitted to hospital on account of a rapidly developing anæmia, with weakness and pyrexia. The child was in a septicæmic state with occasional rigors, sweats, and an afternoon temperature of 102–103° F. He was extremely pale. There was no clubbing of the fingers. The physical signs were essentially the same as at the last examination, in that a machinery murmur was still present in the second left interspace. *In addition a diastolic bruit* was heard down the left margin of the sternum and at the apex. Liver and spleen were both palpable, the latter extending two fingers' breadth below the costal margin. There was dullness at both bases, with diminished breath sounds on the right and absent breath sounds on the left. Urine contained no blood or casts, but albumin was present. A blood count showed 2,300,000 red cells and 12,100 white cells. A blood culture gave a growth of the *Streptococcus viridans*. A diagnosis was made of a patent ductus arteriosus [illegible] The patient died the [illegible] both pleural cavities [illegible] m. The lungs were indurated and œdematous. The heart was enlarged, the left ventricle being proportionately more so than the right. The aorta was slightly larger in calibre than the pulmonary artery. A patent ductus arteriosus was present, and of sufficient size to admit a steel knitting needle. At its pulmonary orifice and extending along its lumen were soft vegetations, and these extended in addition a short distance down the pulmonary artery towards the pulmonary valve. A further small mass of vegetations were present on the wall of the pulmonary artery a little above the pulmonary valve. The pulmonary cusps were normal and devoid of vegetations. At the aortic orifice of the ductus there were no vegetations. Masses of soft friable vegetations were present on the aortic cusps. The remaining valves of the heart were apparently healthy. There was no other cardiovascular abnormality. The spleen was considerably more enlarged than clinical examination had revealed.

Libman considered that a patent ductus arteriosus was *the most important congenital defect* related to an infective endocarditis, and Bedford and Boldero found that infective endocarditis affecting the patent ductus arteriosus occurred more frequently than in any other congenital lesion in 36 cases reviewed by them. This case is interesting in that whilst the wall of the pulmonary artery and the pulmonary orifice of the ductus were involved, the pulmonary cusps were intact and healthy. From published records it appears that only rarely are the pulmonary cusps involved in the infective process. The aortic valves in this case bore masses of vegetations but the wall of the aorta was free of any lesion. Horder describes a similar case in which the pulmonary artery was involved together with the aortic valves, the pulmonary valve being exempt from any lesion. Although in the above case it seems probable that infection occurred first of all at the pulmonary end of the ductus and spread down the artery wall, it is difficult to explain the involvement of the aortic valves except on the assumption of embolic spread of infection to the aortic cusps.

PATENT DUCTUS ARTERIOSUS
WITH A SUPERIMPOSED SUBACUTE BACTERIAL ENDOCARDITIS

By C. Bruce Perry, M.D. Bristol, M.R.C.P. Lond.
COLSTON RESEARCH FELLOW, UNIVERSITY CENTRE OF CARDIAC RESEARCH, GENERAL HOSPITAL, BRISTOL

A sufficient number of cases of patent ductus arteriosus complicated by a superimposed infective endocarditis have been published to show that patients with this congenital defect, like all those with congenital heart disease, are in constant danger of being overtaken by this catastrophe (Horder,[1] Hamilton and Abbott,[2] and Boldero and Bedford[3]). However, the clinical features which at first led to a mistaken diagnosis of pulmonary tuberculosis make the following case worthy of record.

A woman, aged 35, was admitted to hospital with a history of "influenza" seven months ago, since when she had suffered from vague ill-health. She complained of persistent cough, pain in the back of the chest, dyspnœa on exertion, and general malaise. Nothing significant in the family history and no previous illnesses of note.

On examination the heart was found [illegible] enlarged to the left, and there was a strip of [illegible] border of the sternum in the second [illegible] At the pulmonary area there was a loud continuous humming-top murmur and an accentuation of the second sound. A pleural rub was heard at the left base posteriorly. There was a trace of albumin in the urine. The temperature was irregular, at times reaching 101° F., and there were frequent profuse sweats. The blood count showed a leucopenia with a mild secondary anæmia. Sputum examination revealed no tubercle bacilli.

A diagnosis of patent ductus arteriosus with complicating pulmonary tuberculosis was made, and the patient transferred to a sanatorium. Three months later she developed hæmaturia and was readmitted to hospital. The physical signs found were much the same as on the previous admission. Signs in the lungs varied, patches of harsh breath sounds with râles, and pleural friction being heard in parts of the chest from time to time. During the next seven months the fingers became clubbed, there was almost constant hæmaturia and repeated small hæmoptyses, the diastolic part of the humming-top murmur disappeared, and an aortic regurgitant murmur was heard down the left sternal border. The temperature ran a very irregular course, but was never normal for more than three consecutive days. Blood culture showed a growth of *Streptococcus viridans* on two occasions. The patient gradually developed the café-au-lait pigmentation of subacute bacterial endocarditis, and finally died of renal incompetence about eighteen months after the first onset of symptoms. Towards the end the spleen became palpable.

Post-mortem examination revealed a patent ductus arteriosus occluded by vegetations at its opening into the pulmonary artery. The pulmonary and tricuspid valves were normal. There was a large mass of vegetations on the aortic valve extending down to the aortic cusp of the mitral valve. There were pleural adhesions over both lungs, and multiple infarcts in both lungs, the kidneys, and the spleen. Culture of the heart's blood and splenic puncture showed a streptococcus similar to that recovered during life.

The main interest in this case, apart from the association of a congenital cardiac malformation with subacute bacterial endocarditis, is the fact that the repeated small pulmonary infarctions were responsible for the mistaken diagnosis of pulmonary tuberculosis until embolic phenomena in the kidneys revealed the true nature of the condition.

A CASE OF ANÆMIA DURING PREGNANCY

By R. N. C. Smith, M.B. Lond.

LATE HOUSE SURGEON TO THE SUSSEX MATERNITY AND WOMEN'S HOSPITAL, BRIGHTON

A WOMAN, aged 21, came into the Sussex Maternity and Women's Hospital under Dr. J. Shardlow on April 18th, 1932, complaining of swelling of the feet and face, and increasing pallor.

History of illness.—There was no history of anæmia in any relative. The patient had been a perfectly healthy subject, except for attacks, during several preceding years, of slight substernal pain relieved by ordinary measures. The indigestion had been worse for the last three to four months. There was no history of vomiting, diarrhœa, or sore tongue, and none of anæmia. The diet had, so far as was ascertained, been adequate in all essentials, and was in fact, for the class of patient, unusually full. The date of the last menstrual period was not known with accuracy by the patient, but it was believed to have been eight months previously. For six months she had suffered from swelling of the feet, without headache or albuminuria, while for some months she had complained of giddiness.

During the previous 12 days the face had become puffy, and the patient had been confined to bed at home for ten days on a fluid diet with low protein intake. The œdema had to some extent improved on this treatment, but pallor became suddenly noticeable seven days before admission, coincidently with the decrease in œdema, and grew rapidly worse.

Examination.—The patient was a short, well-nourished girl. The face was puffy, and there was considerable œdema of legs and vulva. The feature which at once presented itself to the eye of the examiner was the intense pallor of the face and mucous membranes. Some slight icterus was also noticeable. The tongue was not furred and showed no glossitis. There was no sign of stomatitis. Of lymph glands there was none available to palpation. Examination of the abdomen disclosed a pregnancy of eight months' duration, with the head not as yet engaged. The liver was not felt, but the tip of the spleen could be palpated two fingers' breadth below the costal margin. Over the præcordium there was a systolic murmur and thrill. Blood pressure was 148/74.

Investigations.—0·5 part of albumin per 1000 was present in the urine, together with a fair number of pus cells and a few red blood corpuscles. Urobilin was found to be abundant. Of blood tests, the van den Bergh gave a direct negative reaction, while on indirect test 0·5 unit was discovered (April 20th). The Wassermann reaction was negative. Blood examination on April 19th gave the following result:—

Red cells.. ..	1,095,000	Polymorphs ..	79%
White cells ..	11,400	Lymphocytes ..	16%
Hæmoglobin ..	29%	Monocytes ..	3%
Colour-index ..	1·3	Eosinophils ..	1%
		Myelocytes ..	1%

The red cells showed much anisocytosis, and poikilocytosis, extreme polychromasia, and punctate basophilia. Some nucleated red cells were present, all normoblasts.

Treatment.—On April 19th, the day after admission, the patient began to vomit and complained of epigastric pain, and she continued to vomit until the 25th, making it difficult to maintain any intake of liver extract. On the 21st small hæmorrhages were noticed over the sternum, and on the right forearm and left leg. On the same day treatment by oral administration of liver extract (Liveroid and B.D.H.) was instituted, and total daily amounts equal in value to ¼ lb. of raw liver were retained in spite of the vomiting. A diet as full as could be taken was allowed. Epistaxis occurred on the 22nd and again on the 23rd; 2 c.cm. of campolon liver extract was given intragluteally on the 25th owing to the vomiting excited after oral administration. The injections were continued daily.

Labour and puerperium.—Labour pains began on the 25th, but were very slight, becoming severe the following day. During the second stage air-hunger became intense. Forceps were therefore applied under ether, in analgesic dose only, and a male fœtus of seven and a half to eight months' development in a state of early maceration was removed. There was no sign of anæmia in the child, the mucous membrane being of a normally deep colour. Almost no blood loss attended the birth of the child or placenta, but afterwards the patient developed more œdema round the eyes, extreme orthopnœa, dizziness, and præcordial pain. The temperature rose the same evening, and continued in slight degree until discharge with nothing beyond the anæmia to account for it. On the 21st the liver and spleen were each palpable two fingers' breadth below the costal margin. Dyspnœa on the slightest effort remained for a few days longer, and the heart-rate became very rapid.

Further course of illness.—On April 30th iron in the form of Blaud's pill was given in small doses (grs. x b.i.d.), and as vomiting had ceased the patient was again placed on B.D.H. liver extract (1 capsule daily by mouth). On the morning of the 30th the patient had an attack of blueness with unconsciousness, and on recovery she complained of loss of power in the arms. During the afternoon she developed a maniacal attack, being apparently unconscious of the nature of her surroundings, and filling the ward with loud screams and cries. She became rational, however, before the following day.

The heart, when examined on May 2nd, was found to be showing reduplication of the first sound, with thrill, very loud murmurs, and a rapid rate. The liver edge was extremely tender, suggesting a failing myocardium. The condition caused anxiety for several days. By May 4th, however, the patient was beginning to eat well, though she occasionally vomited after food. She complained of spots before the eyes, and occasions when "everything went black."

After this date improvement gradually set in, and after May 22nd no more liver was given. She thereafter made an uninterrupted recovery, apart from one further attack of epistaxis. When the patient returned home on the 27th the liver was just palpable, and hardly tender, and the spleen could be felt two fingers' breadth below the costal margin.

Iron or liver treatment was not undertaken by the patient after discharge, but when she was seen on July 31st, 1932, there was little sign of anæmia, the colour of the mucous membrane and cheeks being excellent. Blood examination on Sept. 30th gave the following result:—

Red cells.. ..	4,490,000	Polymorphs ..	69%
White cells ..	5,220	Lymphocytes ..	23%
Hb.	84%	Monocytes ..	8%
C.I	0·9		

The red cells were normal in shape and size, and none with nuclei was seen.

I wish to express my thanks to Dr. Shardlow for permission to publish this case, and to Dr. H. M. Galt and Dr. L. R. Janes, of the Royal Sussex County Hospital, for many of the pathological investigations.

MEDICAL SOCIETIES

ROYAL SOCIETY OF MEDICINE

SECTIONS OF THERAPEUTICS AND MEDICINE

At a joint meeting of these sections on Jan. 10th, with Dr. H. Morley Fletcher in the chair, a discussion on the

Treatment of the Anæmias

was opened by Dr. L. J. Witts. In the treatment of microcytic hypochromic anæmias, he said, different chemical combinations of iron had been found to vary greatly in therapeutic activity. The evaluation of remedies was difficult in these anæmias; there was no short cut corresponding to the reticulocyte enumeration in pernicious anæmia. The reticulocyte crisis in a case of microcytic anæmia was prolonged, and the reticulocytes might remain at a level of 2 or 3 per cent. until the anæmia was approaching complete repair. The only way to judge the value of a remedy in these cases was to observe the result on the patient. The compounds of iron, in order of potency, were: ferrous salts, scale preparations, ferric salts, and organic compounds. Organic preparations were almost without effect; the ferrous salts appeared to be much the most potent, especially when achlorhydria was present. Iron and ammonium citrate could be given in doses of grs. xl. a day. If Blaud's pill was given the patient should be advised to swallow the pill crushed. He had endeavoured to determine the effective dose of Blaud's pill, working with series of cases of microcytic anæmia, and had concluded from observation of a series of 18 cases that the smallest dose which could be relied on to give uniformly successful results was grs. xlv. a day. No arsenic, copper, or other inorganic salts were given to these patients, and no liver; a few were given hydrochloric acid. He was convinced that there was no need to add any of these substances to the ordinary diet of an adult in order to make iron therapy effective. Whatever preparation of iron was used, occasional refractory cases would be found which required large doses, but 80 per cent. of microcytic anæmias responded to as little as grs. xv. of Blaud's pill a day. Now that a new preparation of iron for injection had been included in the B.P.C. there would be opportunities for testing its value. The therapeutic dose of iron and ammonium citrate by mouth was 800 mg., and in the case recorded by Hurst in which toxic symptoms arose the dose had been 2100 mg. The therapeutic dose of iron by injection was 16–32 mg., whereas the toxic dose was 48 mg.; the margin of safety was therefore narrow, and he had preferred to avoid the use of iron by injection for that reason. With anæmia occurring at the menopause menorrhagia might nullify the effects of medical treatment; in such cases induction of an artificial menopause produced good results, with disappearance of the anæmia and associated symptoms. In the treatment of pernicious anæmia the cost of remedies was often overlooked. English calf's liver cost 15*d*. a day, and imported calf's liver 8*d*. Dry liver extracts were unpalatable and expensive (36*d*. a day); fluid extracts cost, on an average, 20*d*. a day. Liver extract for intramuscular injection worked out at 10*d*. a day, and was therefore not an extravagance when used on emergency cases, and was much more effective in such cases than liver given by mouth. Desiccated stomach of British manufacture cost 6*d*. a day, though an Anglo-American preparation cost 48*d*. a day. The high claims made for desiccated stomach had been fully confirmed, and it was much the most effective as well as the cheapest treatment for pernicious anæmia at the present time.

RESPONSE IN ANÆMIAS OF DIFFERENT TYPES

Prof. L. S. P. Davidson classified anæmias as follows: (1) anæmias due to nutritional defects; (2) post-hæmorrhagic anæmias; (3) hæmolytic anæmias. It was a mistake, he thought, to treat pernicious anæmia with liver extract or hog's stomach extract alone, once the relapsed stage was past. During the period when the blood count was falling—usually about six months—iron from the hæmolysed blood was retained in the organs. In the recuperative stage, however, as he had been able to show from an autopsy on one of his patients who had been run over, there was no free iron in the organs. He thought, therefore, that patients needed whole liver during the recovery period. He had recently been able to show that fish livers contained a potent substance for the cure of pernicious anæmia; dramatic results had been obtained with extracts prepared from the livers of various fish including cod, haddock, whiting, and monk fish. Extracts made from these sources could be prepared at a much lower cost than animal liver extracts. He had tried the effects of vitamin B, in the form of Marmite, on cases of pernicious anæmia, and had had one or two marked successes with a dosage of ʒ i.-ii. daily, but many failures. Larger doses of the preparation were unpalatable, so that it was unlikely that it would take the place of liver extract. He had obtained excellent results in microcytic anæmia with solid ferrous chloride in daily dosage of grs. v.; this small dose was as effective as Blaud's pill in doses of grs. lx. daily. A preparation of solid ferrous chloride on the market, however, cost the patient 4*s*. a day as compared with 4*d*. a day for Blaud's pill.

EXHAUSTION OF THE BLOOD-FORMING TISSUES

Dr. H. Letheby Tidy thought that, in some cases, exhaustion of the blood-forming tissues might be responsible for the exaggeration of anæmia. He was not referring, he said, to aplastic anæmias. In the type of case he meant the life of the patient might be saved by a blood transfusion. Exhaustion of the hæmopoietic system might be responsible for the condition called "acute febrile anæmia." Cases of polycythæmia, when they developed anæmia, as they sometimes did, might also be examples of such exhaustion. Patients with primary purpura sometimes developed anæmia before any hæmorrhages had taken place; certain cases of pernicious anæmia failed to react to any treatment; and the pernicious anæmia of pregnancy developed without any relation to loss of blood. Some of these were cases in which there might well be acute exhaustion of the hæmopoietic system, and blood transfusion might start them on the way to recovery.

Prof. F. S. Langmead had obtained good results in the microcytic anæmias with Blaud's pill in doses of grs. cl. a day, given in gelatin capsules containing grs. xvii., three capsules thrice daily. He had wondered why the amount of iron which had to be given to be effective was so far in excess of the small amount the body actually needed. He had consulted Dr. R. B. Bourdillon who thought it was associated with the pH of the duodenal contents; where achlorhydria was present, the pH would naturally be unduly high. Achlorhydria was a common factor in those cases which benefited by iron therapy. Perhaps iron in ordinary doses might be equally effective in their treatment if given in association with hydrochloric acid or salts such as ammonium chloride or sodium dihydrogen phosphate, which would tend to lower the pH in the duodenum.

Dr. DOROTHY HARE described a case of microcytic anæmia in which injections of iron had been given for 19 days without benefit to the condition; the patient was then put on iron and ammonium citrate, with immediate and dramatic improvement. She concluded that in some cases the injection of iron was unsatisfactory, or the results were so long delayed that it was not worth while waiting for them.

Dr. JOHN WILKINSON agreed that hog's stomach extract was the best preparation for the treatment of pernicious anæmia. He and his colleagues had been investigating the active principle in hog's stomach and had obtained a good many fractions which appeared to be active. In critically ill cases parenteral liver therapy gave the quickest results. Unfortunately the preparations of liver for injection on the market were extremely variable in their action. Many hog's stomach preparations, too, even though made by reliable firms, were inactive; but once a firm had learned to prepare stomach extract properly the preparations they put out were uniform. This was not the case with preparations of liver for injection. He had tested the effects of copper and manganese in microcytic anæmia, individually and together, and with iron, and had reached the conclusion that better results were obtained with iron alone in most cases. He doubted whether sufficient acid could ever be given by mouth to alter the pH of the duodenum, or affect the absorption of iron.

Dr. SINCLAIR MILLER said that many elderly people with pernicious anæmia found a weekly or fortnightly injection preferable to taking liver or stomach extract daily by mouth; they maintained their hæmoglobin well on this method of treatment.

Dr. E. N. ALLOTT asked whether liver therapy possibly favoured the development of nervous symptoms in patients with pernicious anæmia, and described two cases in which there had been no nervous symptoms beyond slight tingling of the fingers, before liver treatment was begun; subsequently the patients had complained of marked numbness of the fingers which nothing seemed to relieve.

The PRESIDENT asked whether whale livers had been investigated in connexion with the treatment of pernicious anæmia.

REPLY

In replying Dr. WITTS said that if symptoms of subacute combined degeneration developed the dosage of liver or stomach extract must be increased until there was improvement. If the patient was suffering from a shortage of iron during the recuperative stage of pernicious anæmia he should be given iron by mouth, not liver. No one would go on eating liver twice a day for life, and most patients ate just enough to keep them alive, but not sufficient to prevent the development of subacute combined degeneration. This might account for the increased incidence of nervous symptoms. He had seen four patients die following blood transfusion in acute anæmic breakdown, and thought it dangerous treatment. Prof. DAVIDSON thought that there had been a decided increase in the incidence of subacute combined degeneration since the introduction of liver therapy. He had only been able to obtain very slight improvement in the nervous symptoms by enormous doses of liver extract.

PATHOLOGICAL SOCIETY OF GREAT BRITAIN AND IRELAND

A MEETING of this society was held at University College Hospital medical school on Jan. 6th and 7th, with Prof. A. E. BOYCOTT and Prof. C. C. OKELL in the chair.

T. SHENNAN and W. NELSON (Aberdeen) described a cheap and efficient mounting medium for museum specimens composed of liquid glucose, sodium acetate, and thymol.—G. R. CAMERON and C. L. OAKLEY (London) discussed the autolysis and destruction of liver tissue transferred to the omentum, and pointed out that the bile-ducts survived and sometimes proliferated.—R. D. PASSEY and A. LEESE (Leeds) found that kidney placed in the pleural cavity stimulated the growth of the lining epithelium of the superficial lung alveoli.—R. D. PASSEY and J. McD. HOLMES (Leeds) brought forward a number of statistics of the occurrence of carcinoma of the lung, and suggested that the apparent increase in recent years was really due to enlargement of the hospital populations and the activities of the tuberculosis dispensaries.—W. CRAMER (London) had worked out the details of the nephritis found in rats fed on a diet deficient in magnesium: it begins in the glomeruli, probably owing to loss of capillary tone, and leads ultimately to considerable fibrosis.—J. G. GREENFIELD (London) described two examples in young children of an undescribed form of cerebral sclerosis beginning with a degeneration of the interfascicular oligodendroglia.—M. J. STEWART (Leeds) showed some remarkable small arteries found in a fibrous pleura in which there was great overgrowth of the longitudinal muscle-fibres of the intima.—R. MUIR and J. F. HEGGIE (Glasgow) found no hæmoglobin in the bile after the intravenous injection of laked blood; it was, however, present in various toxic conditions produced by phosphorus, phenylhydrazine, saponin, hæmolytic serum, or aniline.—R. MUIR and A. C. AITKENHEAD (Glasgow) found that intraduct carcinoma of the breast is often obliterated by fibrosis which fills up the whole duct.—J. H. DIBLE (Liverpool) described an infant with a penis, a uterus, and a neuroblastoma of the adrenal.—W. M. CROFTON (Dublin) made some remarks on the biology of the cancer cell, and on sarcomatosis in the rat.

K. M. SMITH (Cambridge) gave an account of his X and Y plant viruses, their different properties, the symptoms and lesions they produce respectively and in combination, and their separation by a transmitting aphis.—W. W. C. TOPLEY (London) had repeatedly vaccinated mice with *Bact. ærtrycke*, and then tested their immunity by the inoculation of live cultures. Up to the sixth vaccination they became progressively more resistant, afterwards more susceptible again.—P. HARTLEY and P. BRUCE WHITE (London) described a simple practical method of drying antigens and antibodies in a vacuum with phosphorus pentoxide, by which excellent permanent preparations are obtained.—E. HINDLE and P. BRUCE WHITE (London) gave an account of the preparation of a soluble specific substance from cultures of leptospiras which seemed likely to be of considerable value in separating and identifying the different species and serological types.—K. W. Goadby (London) described the necrotic action of an acetone-soluble lipoid from staphylococcus.—J. Gordon (Leeds) discussed the analysis of the bactericidal action of normal serum.—D. McClean and W. T. J. Morgan (London) showed that the addition of testicular extract to the injection considerably promoted the absorption of antitoxin into the blood.—G. N. Boxhall and F. C. Happold (Leeds) presented some notes on the cultivation of leptomonas and leishmania.—Mary M. Barratt (London) described some curious types of diphtheroid bacilli obtained from the nasopharynx.—C. A. McGaughey (Manchester) demonstrated a number of variants which arose in cultures of Welch's bacillus.—S. L. Cummins (Cardiff) described an interesting imitation of the tubercle bacillus isolated from sputum.—C. E. Dukes (London) discussed the conditions favouring urinary infection after post-operative retention.

Among the exhibits were :—J. C. G. Ledingham (London): the growth phases of the organism of pleuro-pneumonia. R. J. V. Pulvertaft (London): bacterial fluorescence; radium burn of aorta; implantation dermoid in bone; carcinoma of ureter. A. Baker, E. Lepper, and D. Vaux (London): granulosal cell tumours and folliculoma of ovary. E. Lepper (London): macroscopic sections of breasts. C. Price-Jones (London): blood curves. J. A. Boycott (London): a Pijper apparatus for blood corpuscles. D. Vaux and G. Hadfield (London): tumours of parathyroid and pleura. J. M. Ross (London): false mycelium in spleen. G. P. Wright (London): angioma of heart. M. L. Rosenheim (London): periarteritis nodosa. C. C. Choyce (London): radium burn of œsophagus. T. S. Keith (London): extreme dilatation of left auricle: method of mapping the heart post mortem. J. W. S. Blacklock (Glasgow): dermoid cyst in spinal cord; lobulated spleen in infant. J. F. Heggie (Glasgow): hepato-lienography with thorotrast. R. P. Mathers and D. F. Cappell (Dundee): rhabdomyoma of soft palate. T. Taniguchi (Japan): preparations of the parasites of vaccinia and variola. J. S. Foulds (London): umbilical endometrioma; myeloma of skull. J. W. McNee (London): reticulo-endotheliosis of spleen. R. T. Grant (London): arterial angioma causing heart-block. W. N. Goldsmith (London): mycosis fungoides.

LIVERPOOL MEDICAL INSTITUTION

At a meeting of this institution on Dec. 15th, with Prof. R. E. Kelly, the President, in the chair, a discussion on the

Avoidable Wastage Resulting from Industrial Injuries

was opened by Dr. H. E. Moore, surgeon to the L.M.S. Railway. He produced figures showing long incapacity periods amongst men for whom all active treatment had ceased—often for months—and who might have returned to their former occupations after very brief periods if real active treatment had been given at an early stage. Hospital treatment was not sufficiently intensive or persistent; passive treatment, in the form of massage and the like, was in many cases a pure waste of time and energy; the coöperation of the patient in active treatment, which was the biggest factor in recovery, was generally neglected; surgical supervision, which was necessary to give the stimulus and confidence leading to coöperation, was too spasmodic to be effective; men were discharged from treatment before real proof of function had been obtained; and the mental factor present in all and prominent in many was usually ignored.

In National Health Insurance practice, he believed, there was no active treatment available for the many men who needed it for their recovery, and he thought that under the present conditions of panel practice such treatment was impossible. He urged that both the hospitals and the National Health Insurance authorities, who received large contributions from industry, should give this problem their serious attention with a view to forming some service which would reduce the present colossal wastage to reasonable proportions. It seemed to him that the traumatic cases must be completely separated from the ordinary work of the general hospitals. Traumatic centres should be established throughout the country, with specially trained resident personnel, controlled by orthopædic surgeons who had made a specialty of this class of work, and free facilities should be provided for treatment in these centres, for all panel cases which were proving resistant or which required active treatment for their recovery.

Mr. R. Watson Jones agreed with Dr. Moore that far too few workmen recovered so completely from industrial injury as to be capable of early and full re-employment. The traumatic surgeon should solve the problem primarily by raising the standard of fracture treatment, and by remaining satisfied with no result other than a limb indistinguishable from normal. Too often in the past minor degrees of angulation, slight displacements, and the lesser degrees of shortening had been accepted as quite satisfactory results, and only too frequently peri-articular adhesion formation, lateral instability of joints, hypotonicity of muscles, and recurring swelling of limbs had been entirely overlooked. The limb which was indistinguishable from normal could be secured in the great majority of fracture cases by conservative methods, provided that the surgeon placed great reliance on the control of post-reduction radiograms, and showed a greater willingness to remanipulate when necessary a second or a third time. It was equally important that disuse changes in muscles, joints, and circulation should be anticipated and prevented by early functional activity.

Few workmen deliberately malingered from the early days of an injury solely with the object of making money. On the other hand, if minor disabilities were allowed to remain, no workman could be blamed for fearing that his incapacity might increase with the strains of work, or that his incapacity, however slight, might lead to his early discharge on the grounds of inefficiency. The exaggeration and malingering which resulted could have been avoided by achieving a more perfect result. Traumatic neurasthenia and other functional disturbances should often be regarded as avoidable complications of industrial injury. They were due to excessive hospitalisation, or to the adoption of passive methods of treatment such as massage, splints, and apparatus, in place of exercises practised by the man himself, or better still, of occupational activity from the early days of the injury.

Mr. Bryan McFarland said that segregation of fractures was not a complete remedy for the wastage. It was essential to maintain close liaison with a general hospital with its minor injuries. The cases with trivial injuries were often those in which there was delay in returning to full work. Moreover, teamwork was essential in dealing with patients who might have at one time damage to an eye, a spleen, and a femur. Pending the building up of some ideal scheme, such as was suggested at Alder Hey, a very great deal could be done at once by close coöperation between the employer and the surgeon responsible. If an employer would communicate with the surgeon immediately and would work with him, there would be none of the gaps which Dr. Moore had shown to be the cause of wastage. Thus the legal implications would be avoided. For whatever might be said to the contrary, the thought of possible compensation for their injury was immediately present in the minds of certain men, and once they had "started proceedings" a cure was unattainable. Even when cured how could they be proved fit for work? In Liverpool it seemed to be increasingly difficult to prove that a fit man was fit. With adequate early collaboration of surgeon and employer such proceedings would be short-circuited.

It was Mr. McFarland's experience at the David Lewis Northern Hospital that those firms who carried their own insurance coöperated most effectively and with a minimum of wastage; attempts to obtain the coöperation of an insured firm to curtail the unemployable period, or to reduce ultimate disability, were met with the reply "we are insured," while the insurance company answered apathetically, "we are covered." If the employers would do their share, doctors would most willingly assist them.

Dr. J. BERKSON said that just as payment for sickness and payment for claims under the Workmen's Compensation Act were separated, so should the treatment of industrial injuries be separated from the treatment of ordinary illness. Patients with industrial injuries having massage treatment came to their panel doctor for a certificate of incapacity, and when he wished to sign them off as fit, he was told that the patient had to go back to the out-patient department in four weeks, and therefore was not fit to start work. In some cases that went on for months. If the panel practitioner were not allowed to give certificates of incapacity when his patient was attending for treatment at hospital one quite important cause of wastage would be got rid of.

Mr. H. R. BICKERTON thought that employers should not be asked to shoulder any more financial burdens until the profession was satisfied that they were getting full value for the money they were now contributing to the health services of the country. In some districts much had been done to lower the cost of litigation under the Workmen's Compensation Act without hardship to the disputants, and he urged medical men to coöperate with him with this aim in view. The junior men at the Bar might oppose it, but he knew that the senior men would support the medical profession. Many cases as conducted to-day only brought discredit on the medical witnesses and injustice to the genuine workmen.

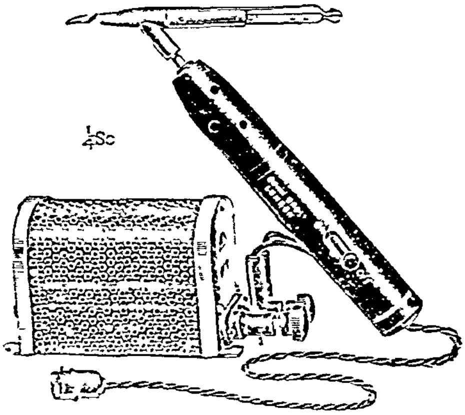
Dr. K. COBBAN, speaking as a general practitioner in a mining district where there were many accidents, said it had been his experience that most patients were eager to get back to work. He did not think that the treatment of the long-standing cases could be carried out by the general practitioner, for it necessitated attendance at hospital; nor did he think that the usual massage treatment carried out at present was efficacious. He would advocate its replacement to a large extent by active movements of the injured parts, and especially by curative workshops.

LUCY BALDWIN MATERNITY HOSPITAL.—Last week Mrs. Stanley Baldwin opened an extension of this Stourport hospital. Sir Julien Cahn, who paid the entire cost of the original building and its equipment, has also borne the cost of the enlargement which increases the number of beds from 11 to 16. The accommodation is divided into one eight-bed ward, one four-bed ward, two one-bed private wards, and two isolation beds. Additional bedrooms have been provided for the nurses and the nursery has been enlarged.

NEW INVENTIONS

METRI-CAUTERY FOR INFECTED CORNEAL ULCERS

THIS instrument is a modification of the design of Prof. Wessely and has been proved valuable (*a*) in arresting septic corneal ulcers that have not yet developed hypopyon; (*b*) in checking the progress of severe hypopyon ulcers and leaving even in advanced cases a very moderate scarring, allowing sometimes a surprising degree of vision. The point should be heated from the main electric supply till the thermometer registers 75° C.; it should not be applied over 85° C. A gentle stroking of the surface of the ulcer for a few seconds usually suffices. The process may be repeated later if any fresh advance is noted, but then, as a rule, only to the advancing edge. The instrument has proved in my hands much less damaging than the actual cautery even at a dull red heat and by the "approach" method—i.e., not touching.

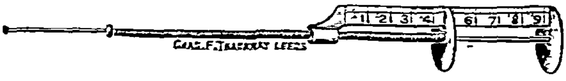


The instrument is made by Messrs. Down Bros., St. Thomas's-street, London, S.E.

A. CHRISTIE REID, M.D. Aberd.

A PLIABLE RULE

CLINICIANS have often found difficulty in the accurate measurement of lesions occurring on curved or obscured surfaces in the mouth, pharynx, and other sites which are inaccessible to the ordinary ruler. To facilitate such investigation I have designed a pliable rule as shown in the accompanying figure. To determine the size of a lesion bend the pliable wire to the desired curve, lay the blunt point on the further edge of the growth, and slide the outer tubing until it is in contact with the nearer edge. Then read the measurement off on the handle. Suitable finger-rings can be provided, and also small slidable indicators for recording several measurements during operations. The instrument is constructed entirely of metal, and it can be easily sterilised. The rule is now being used successfully at the Manchester and District Radium Institute.



Mr. Charles F. Thackray, Park-street, Leeds, is the maker.

DAVID A. HERD, L.R.C.P., L.R.C.S. Edin.

REVIEWS AND NOTICES OF BOOKS

Children's Tonsils In or Out

By ALBERT D. KAISER, M.D., Chief Pediatrician, Rochester General Hospital, N.Y. London: J. B. Lippincott Company. 1932. Pp. 307. 21*s*.

IN order to collect information which might strengthen, or weaken, the belief that a child's development may be retarded by the presence of tonsils and adenoids, and that improvement in the health is likely to follow their removal, Dr. Kaiser has undertaken to study the effect of operation on a large group of children by observation over a period of ten years, and by comparison over a similar period with children whose tonsils and adenoids had not been removed. This has entailed an immense amount of labour, follow-up studies having been made on nearly 5000 children. In two preliminary chapters Dr. Konrad E. Birkhaug, associate professor of bacteriology in the University of Rochester, discusses the anatomy, physiology, and bacteriology of the tonsils; he quotes a large number of bacteriological reports and finds that the *Streptococcus hæmolyticus* is very common in apparently healthy throats, not only on the surface of the tonsils, but in the crypts, and he mentions the work in England of J. Ramsay and C. M. Pearce, who found the hæmolytic streptococcus in 78 per cent. of cases examined by their method of tonsil puncture. A. L. Bloomfield and A. R. Felty also found, during an epidemic of tonsillitis among nurses at the Johns Hopkins Hospital, that hæmolytic streptococci were the predominating organisms, but that the number of colonies obtained from any individual case bore no relation to the severity of the clinical symptoms and signs. Such findings make it difficult to accept bacteriological evidence of tonsillar disease. Dr. Kaiser then considers the effects of operation. He finds that uniformly good results can be expected from the removal of hypertrophied or infected adenoids on children who have nasal obstruction or catarrhal or suppurative otitis media.

The greater part of the book, however, is taken up by the analysis of the results of tonsillectomy on the incidence of a large number of diseased conditions. It must suffice here to enumerate them: sore-throat, the common cold, laryngitis, bronchitis and pneumonia, cervical adenitis, ear infections, sinusitis, scarlet fever, diphtheria and other infectious fevers, rheumatism, chorea and heart disease, nephritis and pyelitis, tuberculosis, dental caries, asthma and hay-fever, malnutrition, anorexia, cyclic vomiting, diabetes, general intelligence, and mental deficiency. A few of his conclusions are noteworthy. On the important question of the rheumatic affections, he finds that about 30 per cent. fewer cases of rheumatism occur in children whose tonsils have been removed than in control children where no operation was performed, but that, when a rheumatic infection has once manifested itself, tonsillectomy does not safeguard the child against recurrent attacks. The occurrence of nephritis is somewhat less in tonsillectomised than in unoperated children, though the difference is not great enough to warrant much enthusiasm. The removal of infected tonsils after an attack of acute nephritis is to be desired. The effect of tonsillectomy upon the incidence of scarlet fever is statistically insignificant and, in children whose tonsils have been removed, there is no evidence that the disease is less severe or less likely to cause complications; but a child with his tonsils removed is definitely less susceptible to diphtheria, and the operation hastens the elimination of organisms from the throat of the diphtheria carrier. There is little effect on the occurrence of measles, chicken-pox, mumps, or poliomyelitis; or, somewhat unexpectedly, on the incidence of repeated attacks of unexplained fever. In contradistinction to removal of adenoids, tonsillectomy after the fifth year offers very little protection against primary and recurrent infections of the ear, and mastoid involvement after otitis media occurs with equal frequency in the presence and in the absence of tonsils.

After due allowance has been made for the limitations of the statistical method the book remains a monument to the author's industry and research. In spite of its flippant title, it is a serious contribution to medicine, which will greatly assist in confirming or modifying our views on the value of tonsillectomy in individual cases.

Effets éloignés du pneumothorax thérapeutique

By L. DE WECK, Médecin-Chef du Sanatorium Victoria (Montana). Paris: Masson et Cie. 1932. Pp. 129. Fr.16.

Dr. de Weck's work is based on the study of 51 patients who completed a course of treatment by artificial pneumothorax during the period 1911 to 1920. This record of the durable relief or lasting cure of consumptives by collapse therapy should help to dispel the doubts still expressed as to its permanent value, and should encourage those whose faith in pneumothorax treatment has not yet the support of long experience. The book is more than a mere record of therapeutic successes. Dr. de Weck has made a noteworthy contribution to the study of the "de-inflation" period, of the response of lungs and pleura to the negative pressure which results when refills are discontinued, and of the complications which sometimes accompany pulmonary re-expansions. Reproductions of radiograms illustrate the text and add to the value of this excellent little book.

Diseases of Old Age

By F. MARTIN LIPSCOMB, M.R.C.P., Major R.A.M.C., Deputy Surgeon at the Royal Hospital, Chelsea. London: Bailliere, Tindall, and Cox. 1932. Pp. 472. 12*s*. 6*d*.

WHEN the student or resident leaves his training hospital he is rather inclined to think of any sick person over the age of 65 as someone to be got rid of as soon as possible, either by means of a bottle of medicine or an "infirmary order." His consternation on starting practice to find that a large proportion of his time is taken up by old people is enhanced by his difficulty in obtaining information to fill this gap in his education. Dr. Lipscomb has endeavoured to give a straightforward clinical account of those maladies which have a high incidence in old age, and those which are conspicuously modified at this period of life or are of special diagnostic interest. Though the book is primarily medical, it includes a chapter on some surgical aspects of old age as well as on its general management; ætiology and pathology have been reduced to a minimum. Mistakes are few; it is not clear, however, to what the reference to page 104 refers in the chapter on the urinary organs. The best sections are those on the heart, the nervous system, and the mind, and they are illustrated throughout by the author's personal experiences among the Chelsea pensioners. Not enough stress, perhaps, has been laid on the extreme difficulty of regulating an aged person's bowels to the mutual satisfaction of the patient, the nurse, and the medical attendant, nor on the fact that the low abdomen of the old reveals quite a number of masses apt to be diagnosed by the unwary as carcinoma. Even if such a diagnosis should be correct it would probably be unwise to mention it, since carcinoma grows so slowly in the very old that they may easily die of some intercurrent disease before the growth has caused any symptoms. This book is essentially practical and well balanced, of great interest to all, but especially suitable for the young practitioner.

The Gold-headed Cane

By William Macmichael, M.D. Edited by Prof. Herbert-Spencer Robinson. New York: Froben Press Inc. 1932. Pp. 223, with index and copious notes. $3.50.

The sixth edition of William Macmichael's well-known and fascinating book has appeared in attractive form in the series entitled Historia Medicinæ now being issued from the Froben Press. The edition is edited, with explanatory and illustrative notes, by Prof. H. S. Robinson, well known as an expositor of English literature in American university centres, and author of "English Shakespearian Criticism in the Eighteenth Century," and other works of literary interest. This new edition contains the original illustrations to the 1828 edition—the second edition—as well as hitherto unpublished portraits of Macmichael and details of his life and family. Macmichael was an interesting man. He graduated M.D. at Oxford in 1808, was elected Radcliffe Travelling Fellow in 1811, and interpreted the responsibilities incurred by visiting during the next five or six years Russia, Turkey, the Danubian Principalities, and Palestine. He was elected a Fellow of the Royal College of Physicians of London in 1818; in 1824 became registrar to the College, and while holding that office had the happy idea of publishing the biographies of five leading London physicians of the eighteenth century who in succession had been in possession of a gold-headed cane, now the property of the College. The five physicians were John Radcliffe, Richard Mead, Anthony Askew, William Pitcairn, and Matthew Baillie, and on the death of the last the cane was presented to the College by his widow. It bears on its crutch-handle the arms of its five distinguished owners.

The first edition of "The Gold-headed Cane" appeared in 1827, and a second appeared in the following year with considerable additions, and has formed the text of subsequent issues. Throughout its life of over a hundred years the work has met with such popular favour that it has earned fairly the hard-worked epithet of a classic. The device by which the cane is made the describer of its five famous possessors—a popular narrative method a hundred years ago—was carried out with such literary skill that constantly the reader feels that he is listening to the views of a human contemporary of the famous doctors, so large a proportion of whose patients were famous also. Radcliffe, after being in ill odour with King William and Queen Mary, refused to attend Queen Anne in her last illness apparently because he was not properly summoned; Mead, friend and physician of Sir Isaac Newton and Pope, would not continue to treat Sir Robert Walpole unless a political prisoner, a colleague, was pardoned; Askew knew all the great scholars of the day, and declined to be physician to Queen Charlotte on her arrival in England (the "Cane" is the authority for this statement). The lives of Pitcairn and Baillie do not suggest that the Cane when in their possession was carried into quite such aristocratic circles or conducted with quite such a sense, due or undue, of importance, but Pitcairn and Baillie were fine representatives of the profession in the eighteenth century, and the latter made valuable additions to pathological knowledge.

The special value of the new edition of "The Gold-headed Cane" lies in Prof. Robinson's profuse and accurate notes. Practically every personal reference made by the Cane to a vast number of distinguished persons with whom its five owners had been associated is explained by biographical notes, quotations, and literary allusions. Students of medical history will be grateful to the learned and industrious editor.

Food, Health, Vitamins

Fifth edition. By R. H. A. Plimmer, D.Sc. Lond., Professor of Chemistry in the University of London at St. Thomas's Hospital Medical School; and Violet G. Plimmer. London: Longmans, Green and Co. 1932. Pp. 143. 3*s*.

This useful and inexpensive little book is brought up to date in a new edition, which contains notice of all the most important contributions to the subject which have been made since the appearance of the last edition. These include particularly work on the relation of carotene to vitamin A and attempts to isolate the antiscorbutic vitamin. There is a brief useful addition on the separation of vitamin A from vitamin D, and of B_1 from B_2, and the section on pellagra has been considerably modified. Hypervitaminosis D receives attention, and stone in the bladder is dealt with from a different point of view. There is no bibliography, although many names are mentioned, followed by a date in brackets; in a few instances the full reference is supplied in a footnote.

1. Management of the Sick Infant

Fourth edition, revised. By Langley Porter, B.S., M.D., M.R.C.S. Eng., Professor of Clinical Pediatrics; and William E. Carter, M.D., Instructor in Pediatrics at the University of California Medical School. London: Henry Kimpton. 1932. Pp. 763. 42*s*.

2. The Infant: A Handbook of Management

By W. J. Pearson, D.M., F.R.C.P., Physician-in-charge of the Children's Department, University College Hospital; and A. G. Watkins, M.D., M.R.C.P., B.Sc., Physician in Children's Diseases, Cardiff Royal Infirmary. London: H. K. Lewis and Co., Ltd. 1932. Pp. 47. 2*s*. 6*d*.

1. Preparation of a fourth edition of this ambitious compendium has enabled the authors to include references to almost all the most recent mechanical aids to the treatment of disease in childhood. English readers will be somewhat staggered at their number and diversity. Illustrations are given of the Roth-Barach carbon-dioxide-oxygen tent, the electrically heated Hess bed, and Hess transportation bag for premature infants, and of both hydraulic and electric breast-pumps. The technique of nursing an infant on the breast, however, is dealt with in exactly six lines. The section on "the radiogram" is also very inadequate. Considerable space is devoted to methods

of investigation as well as those of treatment, and it is rather surprising to find a detailed description of the diagnosis of intussusception by the barium enema whilst the subject of encephalography is not even mentioned. Again, we note that of four directions given for dealing with a choking infant one is to call a laryngologist and another is to read Chevalier Jackson's "epochal work" on bronchoscopy.

The book is divided into three sections, the first dealing generally with such subjects as "cough," "vomiting," "prematurity," and "nutrition," the second being a systematised though slightly hurried account of disease in early childhood, and the third giving a detailed description of the methods employed in its investigation and treatment. Of these sections, the last is unquestionably the most valuable. Not only is it well illustrated, but the various methods are for the most part concisely and clearly described, and the authors have collected in one volume a great deal of material that is nowhere else available. This section alone should make the book of value to all who have to deal with infants, either in hospital or private practice, and should make it as well known to pædiatricians in this country as it is in America.

2. Of the numerous books which have appeared recently on the subject of infant management, this probably succeeds in compressing most information into the smallest space. Much of the matter is tabulated, but is nevertheless presented in a readable way. A particularly useful section is devoted to the relative cost of various artificial foods, which should be appreciated by the practitioners, infant welfare workers, and others to whom the book is specially directed. We are inclined to think that more than two and a half pages might well have been devoted (perhaps at the expense of one or more of the several blank pages provided for notes) to the technique and difficulties of breast-feeding in view of the emphasis on the importance of mother's milk with which the first chapter opens. Apart from this, however, the book succeeds in its object of making readily accessible information which has usually to be sought in large text-books.

Growth

By the late J. LORRAIN SMITH, M.D., D.Sc., F.R.S. Edited by J. S. HALDANE, C.H., M.D., F.R.S. Edinburgh: Oliver and Boyd. 1932. Pp. 135. 6s.

No one with any familiarity with the subject will put this book down and feel that they have learned many facts about growth which they did not know before. They will be less satisfied, for their natural reaction will be to say to themselves, "that is an interesting idea, I should like to have a talk with him about that," and they will have a good many questions to ask and things to think about. And they may well see for the first time that some of the simplest phenomena of growth are not nearly as simple as they seem. Lorrain Smith would, we think, be well content to have roused the curiosity of those who read the fragmentary chapters and notes which he had written towards a formal treatise, and which have been gathered up by his daughter and life-long friend. They do not form a coherent whole, there is a good deal of repetition and in some places obvious lacunæ. Except for the tolerably complete chapter in which he argues for the mutative hypothesis of malignancy, they are more like small talk about growth—just the sort of talk which his friends would expect from the man who sits writing at his study table in the delightful frontispiece—gentle, suggestive, in flashes of some happy phrase sometimes illuminating and never wholly conclusive; he was too much of a philosopher for that. The part of the book which he had sketched out is mostly about the growth of individual cells, from their beginnings as independent units to their full maturation, and he evidently thought a good deal about the examples in which maturation means death, as in the skin and the red blood corpuscles. But he would have us wonder how it is in the growth of the skin, for example, that only one of the two cells which come by the division of a germinative cell progresses to the stratum corneum, while the other remains to divide again. It is indeed a problem; no wonder Lorrain Smith wanted to get more pathologists interested in it. For, as he truly says, cell growth is one of the really fundamental things in their science.

British Journal of Children's Diseases

THE October-December issue (vol. xxix.) contains a paper on Experimental Studies on the Filtrable Microbe of Scarlet Fever and on Activators in Relation to Hæmolytic Streptococci, by Dr. T. Toyoda and Dr. Y. Futagi, of the Japanese Government Isolation Hospital at Dairen, Manchuria. They first discuss Di Cristina's theory concerning the filtrable microbe of scarlet fever which was supported by Caronia and Sindoni. Like Bürgess and Meyer in Germany the Japanese observers carried out investigations whose results contradicted those of the Italians. As regards the question as to whether any other factor than streptococci is needed in the ætiology of scarlet fever, Toyoda and Futagi failed to discover the filtrable microbe described by Zlatogoroff on the diphtheroid bacillus of Mandelbaum, who regard their organisms as activators of the hæmolytic streptococcus of scarlet fever. Toyoda and Futagi conclude that there is no necessity to consider some other unknown microbe besides the hæmolytic streptococcus as responsible for scarlet fever.—Dr. G. T. Cook contributes a paper On the Association of Pulmonary Changes with Rheumatic Pericarditis, based on a study of the literature and observations on 13 personal cases. He emphasises the frequency with which pulmonary signs are found in association with acute rheumatic pericarditis, and states that they occur much more frequently on the left side than on the right. The pulmonary condition which may arise quite independently of any pleural or pericardial effusion shows considerable variation both in the severity of the signs and symptoms and in their duration. The histological appearance of the lungs is these cases is one of collapse and passive congestion rather than that of a specific inflammatory condition. Cook suggests that the pulmonary condition is an active massive collapse of a portion of the lung, being due to reflex disturbance of the vagus and sympathetic innervation of the lung from inflammation of the pericardium.—In a paper entitled A Pedigree of Hæmophilia; Dr. W. J. Rutherfurd records his observations on a pedigree of five generations in which seven cases of hæmophilia were known to have occurred. Of the 66 individuals in the pedigree there were 54 whose sex was reported, 21 being males and 35 females; 14 of the 66 died in infancy or early childhood.—In his paper on Some Pædiatric Eponyms, IV.—Sydenham's Chorea, Dr. W. R. Bett refers to Hecker's account of epidemic chorea in the Middle Ages, and reproduces Sydenham's description from the Schedula Monitoria, illustrated by a portrait of the English Hippocrates.—Dr. E. W. Goodall records A Case of Recurring Serum Rash in a girl aged 2 years, who after an injection of 12,000 units of antitoxin for diphtheria developed six times in the course of six weeks an erythematous rash such as is common after serum injections, with an interval between each rash. There was no pyrexia nor any other symptom beyond the occurrence of an abscess at the site of injection with any of the rashes.—The annual index in this issue provides a guide to contemporary pædiatric literature.

THE LANCET

LONDON: SATURDAY, JANUARY 14, 1933

MASKED HYPERTHYROIDISM

For the clinician one of the most important advances made of late in our knowledge of thyroid disease is the discovery—or perhaps, more accurately, the rediscovery—of a condition which has been called in America "masked hyperthyroidism." Elsewhere in this issue Dr. John Towers records a series of cases of this type. From work done chiefly in America we now know that thyroid secretion may do no little damage to the heart in the absence of those classical signs, such as changes in the eyes, wasting, nervousness, and obvious goitre, which can be seen at a glance, and on which the diagnosis of Graves's disease has in the past depended. All these symptoms may be absent in a patient suffering from heart failure, and yet the failure may be correctly attributed to the action of an abnormal thyroid secretion, perhaps over a long period of time, and certainly on an organ rendered susceptible by increasing age. The adjective "masked" is therefore well applied. The condition is seen, apparently, only in people at or past middle age, and while it is not a new idea that the classical signs of thyroid intoxication tend to be much less conspicuous at this age than in the young, the cases covered by the new term show these signs only in minimal degree or not at all. T. P. Dunhill's thesis that the infinite variety of the clinical picture of thyroid intoxication can be explained by variations in three factors—the stimuli, the thyroid gland, and the organs affected by the disordered secretion—is an attractive one, and it may be that masked hyperthyroidism can be best accounted for along these lines.

Most often the patient will present herself—the female predominates, but the male sex is not excluded—with symptoms suggesting heart disease, especially palpitation. This may occur with sinus tachycardia, sometimes with premature beats in addition; with auricular fibrillation, which is likely to be paroxysmal at first; or even with normal rhythm without tachycardia. Congestive heart failure of thyroid origin is found only in association with permanent auricular fibrillation. Whether the thyroid heart enlarges or not, and whether or not any histological changes, specific or otherwise, are produced in the myocardium, are matters that have been controversial for some time. From the practical point of view they do not affect the clinical fact that the thyroid can be responsible for cardiac disturbances up to the point of congestive failure. What, then, are the points which will make the diagnosis probable? The eyes show no prominence but a slight staring expression, or sometimes a momentary lift of the upper lids revealing the sclerotic will be a suggestive sign. There may be a salmon tint of the skin, fine tremor, and minimal enlargement of the thyroid, or even undue hardness alone. Improvement with administration of iodine, and increase in the basal metabolic rate (though a normal rate does not negative the diagnosis) will be additional evidence. The character of the apex-beat and of the first sound may give a clue, as is emphasised by Dr. Towers. The persistent finding of a high pulse pressure will also be suggestive. Here it may be mentioned that thyroid intoxication has sometimes been considered an occasional cause of diastolic hypertension; the failure of thyroidectomy in two of Dr. Towers's cases with high blood pressure of this type to lower the pressure, while relieving the certain symptoms of excessive thyroid secretion, does not support this view. Finally, the shape of the heart on X ray examination may clinch the diagnosis.

It cannot be denied that the evidence for incriminating the thyroid in some cases of cardiac disturbance is at times slender; yet, in others, the diagnosis can be certain, and appropriate treatment may mean cure, whereas a mistaken diagnosis may mean early death. The first essential in diagnosis is to bear in mind the possibility of a goitrous origin of the symptoms in any middle-aged patient with palpitation, paroxysmal auricular fibrillation, or permanent fibrillation with congestive heart failure. Once the diagnosis of masked hyperthyroidism with heart disease is made a partial removal of the gland is always warranted. Not very long ago cases of cardiac failure associated with thyroid disease were refused operation on the ground that it was too dangerous. With further knowledge of the true risk, and improved methods of pre-operative treatment, this view has been reversed; and it may be said that the greater the heart damage, the slighter are the chances of recovery without operation.

◆

TUBERCULOSIS IN SOUTH AFRICAN NATIVES

The committee appointed seven years ago to investigate the extent of tuberculosis in South Africa, more particularly in its relation to native races, and to formulate measures for the determination of the morbidity and mortality from tuberculosis amongst the gold mining population of the Rand, has issued a report, summarised on p. 100, which merits careful study. It provides an extensive survey of the South African native from practically every angle bearing upon tuberculosis—anthropology, epidemiology, pathology, and clinical medicine. Since the natives working on the goldfields now number over 200,000, and the incidence of tuberculosis among them is estimated for the period 1928–29 at 6·62 per 1000, the mine population directly affected by this study is large; and in view of the constant migration to and from the mines the study has an indirect bearing on the health of natives in their own territories. The inquiries were conducted on a colossal scale. Intradermal tuberculin tests were made on 94,000 native mine workers; a single injection of 1/10 c.cm. of 1/5000 O.T. was used at first and the dose was subsequently reduced. The important facts which emerged from these tests were :—

(1) With the strengths of tuberculin used only 65 per cent. of the subjects yielded a positive reaction.

(2) Despite a probable under-estimate of the true numerical strength of the positive group, the incidence-rate per 100,000 of tuberculosis was more than twice as high in the positive group as it was in the negative group.

(3) The more positive the reaction the greater the liability to tuberculosis.

The natives tested were all carefully examined, and if tuberculosis was confirmed they were repatriated and advised not to return to the mining fields. Another group of natives investigated was a collection of chronic cases of tuberculosis detected by mine medical officers after the natives had worked five or more years. Periodical weighings are found to be the most practicable method of early diagnosis, and by the Regulations made under the Miners' Phthisis Act of 1925 any native showing a marked decrease of weight (5–6 lb. or more) between two consecutive weighings, must be referred for special examination. For various reasons no attempt is made to undertake prolonged systematic treatment in the mine hospitals, so that the medical officer has, therefore, only to make up his mind whether or not the native —who mostly clamours to be sent home as soon as he is put off work—is fit to be repatriated. The patients retained in hospital are those who are deemed too ill to travel. Little can be done for these cases, which generally end fatally in a very short time. No complete return of survival periods was obtainable, but figures submitted by four mine hospitals showed that for 145 consecutive cases of deaths from tuberculosis the average survival period was 28 days. An interesting comparison between native and European tuberculosis is afforded by records of 200 consecutive autopsies on tuberculous natives (without silicosis) and 200 autopsy records supplied by the Victoria Park Hospital, London. In the natives, for example, cervical glands were more rarely, other glands more commonly involved, and involvement of the spleen, liver, and other abdominal organs was far more common among the natives. The writers of the report regard these native cases as approximating closely to the type of acute tuberculosis of non-immunised races, which was first differentiated by BORREL as an outcome of his classical investigations in Sengalese recruits. The South African mine native is not, however, as they have shown, completely virgin soil. The actual extent of the incidence in native territories is unknown, no relevant vital statistics being available. Dr. PETER ALLEN, medical superintendent of the Nelspoort tuberculosis sanatorium made for the committee a tuberculin survey which revealed a high degree of tuberculosis amongst the southern group of the native territories and a lower degree in the northern group. Between the ages of 5 and 15 tuberculisation was more marked in girls, who do not go to the mines, than in boys; at later ages the boys "caught up." Out of 694 natives repatriated from the mines with tuberculosis during the years 1926–29, Dr. ALLEN followed up 475, and his records make grim reading. Two years after repatriation 60 per cent. were found to have died, and of the rest 4 per cent. were fit to return to heavy work, 10 per cent. were not fit for any work, and 26 per cent. were fit for light work at their homes. Although it cannot be assumed that the repatriated tuberculous plays no part in the spread of the disease in the girls, it is equally impossible to believe that he is the sole agent responsible for the wide dissemination. The economic situation in the native territories often forces the native to seek work from the European in industries where he may either acquire a primary tuberculous infection or light up a smouldering lesion which he already possesses.

The inferences to be drawn from these exhaustive inquiries are of deep significance. The urgent need for a radical improvement in the medical services in the native territories has led the committee to advise the appointment of a travelling medical officer with the special charge of dealing with tuberculosis amongst repatriated workers. Anti-tuberculosis measures, they say, should be provided in urban locations, and the committee are also of the opinion that there is scope here for investigation of the value of a B C G vaccine amongst the children of urban locations where tuberculosis is rife. They recommend that travelling conditions to and from the native territories should be investigated, and note that there is still room for improvement in the accommodation provided in the mine compounds; notably in the direction of fewer occupants in each room and of better separation between individual bunks. A period of rest and a light meal during working hours, which involve an average of ten and a half hours underground and eight hours' continuous work without food, is recommended, with the addition of vitamin A to the dietary. The protection of natives from sudden changes in air temperatures and velocities by suitable ventilation or by the provision of extra clothing is also advised. Special anti-tuberculosis measures on the mines should include a stringent initial examination to exclude natives arriving with latent tuberculous lesions; a gradual acclimatisation to strenuous mine work; periodical examination of all natives with over five years' total mining service; and continuous efforts to improve on the present admittedly high standard of dust suppression without increasing humidity in the mines. Finally, in order to ensure continuity of policy the committee propose the appointment and maintenance by the Chamber of Mines of a standing advisory health committee. As the committee remark, "tuberculosis of the native is not only a native problem. It is the problem which touches the health of the white community very nearly and will do so to an increasing extent. . . . Those who take the long view will agree that the sooner the length and breadth of the problem is made better known through the collection of vital statistics the better for the Union of South Africa."

No one who studies this report will fail to be stirred by the plight of the native infected with tuberculosis. The degree of immunisation acquired by the South African native seems to be about that of a European child and falls far short of that of a human adult; and the protection afforded to him when he seeks work entailing risk of infection must be designed on this assumption. Prof. Lyle Cummins, in a commentary which is incorporated in the report, discussing the failure of the authorities to provide an adequate medical service for the black populations in the native territories, sums up well (p. 290) the impression left by the report. He says "to one who is merely a visitor to South Africa, the sight of such a dependant population, giving so much and obtaining so little in return, is calculated to arouse feelings much deeper than surprise." That much can be accomplished on relatively simple lines is proved by the success of the medical services organised by the mining companies for the natives during their actual periods of work on the Rand; a provision which offers a sharp contrast to the almost complete lack of medical and surgical facilities in the Transkei and Ciskei, where the witch-doctor still exploits the credulities and the necessities of the sick. Through nearly half a century of trial and error the mining industry has learnt its lesson—that a healthy native working population is worth paying for. The issue of this report is timely, since gold mining in Kenya must involve the application of knowledge gained in the Transvaal if the native labour corps recruited for the development of the mines is to be protected as far as possible from the dangers associated with this work.

◆

PAIN AND THE DOCTOR

August Bier once wrote, "The doctor should cause no pain"; and the saying, though a hard one, merit attention, coming as it does from one responsible for numberless appliances, large and small, for relieving or diminishing painful or uncomfortable sensations. The late Dr. Albert Krecke,[1] in an intimate study of doctor and patient which well describes the state of mind of sick people, echoes the warning given scores of times to the medical student, and as often forgotten: "Do not touch; look." It was one of the heritages of C. B. Lockwood's teaching that his pupils never forgot this maxim. But beyond the skilful use of eyes there must also be the skilful use of fingers. Speaking last term to students of this art of handling living flesh, Mr. Wilfred Trotter[2] said:—

> "Here at any rate is something everyone can teach himself. Hands coördinated to smooth, firm and gentle movement are to the sick body the complement of the attentive receptive mind. . . We must not use the excuses that patients expect to be hurt, that they accept with resignation the clumsy dressing of wounds, and allow themselves to be examined by a series of crude prods and bangs. When you ask a patient if you are hurting him, nine times out of ten he will reply with touching cheerfulness 'Not yet, doctor.' What a succession of iron thumbs is disclosed by that answer!"

This passage gives colour at least to the accusation lately made by a lay writer, Mr. Gerald Heard,[3] that the medical profession does not take pain seriously enough.

Mr. Heard is explicit. "Quite half of the people who stay away from you when they should come to you," he says, "are staying away frankly because they dread torture. They will stay till too late because they believe that you are not actively concerned to save them suffering—you are exclusively concentrated on trying to save life." We know that this statement is not true, but like pain itself it is a genuine symptom of disorder in our relation with patients. There is, in other words, something in the criticism. In his gladness at finding a warning signal that he can read and act upon, the doctor may sometimes forget that the patient, after all, does not come seeking a sign. Mr. Trotter, in the address already quoted, emphasises the difference in aim:—

> "The ordinary patient goes to his doctor because he is in pain or some other discomfort and wants to be comfortable again: he is not in pursuit of the ideal of health in any direct sense. The doctor on the other hand wants to discover the pathological condition and control it if he can. The two are thus to some degree at cross-purposes from the first and unless the affair is brought to an early and happy conclusion this divergence of aims is likely to become more and more serious as the case goes on. The good doctor therefore has to learn to serve two objects at the same time—the diagnosis and treatment of the patient's ailment on one hand, and to keep him comfortable on the other."

If Mr. Stephen Leacock is to be believed—some of his pungent comments are quoted on p. 121 the modern doctor fails very lamentably to achieve this double service. And Mr. Leacock's satire certainly contains a regrettably large grain of truth. "The best thing that could happen to you," said an experienced practitioner to his young colleague, "would be to have a serious illness early in your career"; and one cannot help thinking that most of us would be the better (professionally) for serious illnesses at regular intervals all our lives. If the doctor really had the patient's point of view would he not be a little less light and airy about pain? Would he not ask himself more often whether it was really necessary, whether the new resources of medicine could not overcome it, whether the benefits of non-interference were worth the price? Sometimes, perhaps, we accept too readily the traditional view that pain is something which cannot be avoided. The patient knows that he can grin and bear it, if necessary; but he asks that the sacrifice of his comfort should be justifiable—justifiable not on some antique conception of the inscrutable ways of Providence, but upon the principles of modern medicine, interpreted and applied with common sense. Where cure is actually impossible or unlikely there is much to be said for being allowed to die at ease in Zion and to smile.

[1] Von Arst und seinen Kranken. By Alfred Krecke. Munich: J. F. Lehmann. 1932. Pp. 378. R.M.6.

[2] Univ. Coll. Hosp. Magazine, Sept.–Oct., 1932, p. 212.

[3] Middlesex Hosp. Jour., July, 1932, p. 185.

Pain occupies a patient's attention in the present, and even when it is past its shadow darkens the future. A painful convalescence is likely to be a slow convalescence; recovery may be slow because pain focuses the mind on the existence of something wrong; the thoughts are anchored to disease. But it is the doctor's thoughts that should be so anchored; the pain should primarily be *his* concern, and as soon as he has interpreted its meaning he should take steps to abolish it. It may be answered that pain, since it is subjective, cannot be accurately measured; the language used to describe it, though at times full of colour, is vague and metaphorical and may be misleading. There can be little doubt, however, that were it possible to register pain in the same way that it is possible to register body temperature, far more notice would be taken of it. The stoic's mask would be snatched from him, with the result that what he describes as a mere nothing would have a unit placed before the cipher and possibly another cipher added. He would no longer be able to suppress the painful truth, and the physician would in consequence be in a better position to deal with it. We should be able, too, to gauge the problem of different individuals' reaction to pain, to admit more willingly than we do that certain people, and not always those who pride themselves on it, are far more sensitive than others.

Pain is important. None the less we doubt if it is the principal deterrent from medical treatment, as Mr. Heard makes out. It is chiefly the unknown that people dread—uncertainty, a strange environment, the interruption of a familiar routine. Pain, if necessary, most of us will accept; we ask, however, that we shall be treated as individuals who suffer, even though the doctor may remember us only as cases he has cured.

◆

THE MEDICAL STUDENT IN THE UNITED STATES

THE Association of American Medical Colleges appointed a commission, as long ago as in 1925, to study the various principles under which the medical curriculums of the country and the issues of qualifications were conducted. The commission was instructed to make suggestions for necessary reforms, and especially to note the directions in which action could be taken towards the improvement of university education in conformity with the needs of existing society. The Association, in coöperation with the American Medical Association, has already regulated the educational standards which the various States must bear in mind when issuing licences to practise, when a revision of conditions was found necessary with considerable frequency in order to meet abuses which had grown up under proprietary and commercial medical schools, certain of which had degenerated into manufactories for the supply of imitation degrees. Both Associations are to be congratulated on the success of their joint action, for during the past 25 years professional medical training in America has undergone radical improvement, as will be readily gathered from the report of the 1925 Commission which has just been issued,[1] while the scandal of bogus medical institutions has largely if not entirely disappeared. The personnel of the commission comprised recognised authorities upon medical education and university organisation, and the financial support was derived from the Rockefeller Foundation, the Carnegie Corporation, the Josiah Macy, Jr., Foundation, and the American Medical Association.

While from the report we can see how much has been done, we can see, also, how much remains to do. Although the various efforts to standardise medical education and to reform the bodies responsible for it have led to certain minimum requirements for proper instruction being universally met, there remain wide differences, both in ideals and in organisation, among the institutions, some of which are among the great medical centres of the world and some of which may have survived the scrutiny of the Associations not without a struggle, but are now proving their worth. The differences are found not only in buildings, equipment, and financial stability, but in the facilities and amenities forthcoming for ward and laboratory training, and represent the handicaps under which certain of the schools are labouring. This position has been made clear during the prolonged sittings of the commission by the regular issue of ad interim reports, from which could be gathered seriatim the nature of the problems with which the commission was dealing and the needs of the community to meet which the medical profession had to be equipped. The place of post-graduate education and the due scope of specialism had both to be visualised, as well as the conditions under which the students were trained and the hospital appointments were held, before concrete recommendations could be justified. These matters are discussed in the report before the details of the curriculum are taken up, in order that any reflections upon the training may be related properly to the entire professional life of the physician. In consequence, we get the feeling that the advocacy of certain principles has had throughout the common intention to render the doctor useful to the community in his sphere. For the same reason reference is made only incidentally to particular scientific work, to staff organisation, and to finance. All of these, as they influence the training of students, the selection of teachers, and the quality of instruction, are held to be so generally appreciated that to discuss them is superfluous. The value of the document lies in the resolve to regard the life of the doctor as an entity, and to present a picture of the training that should fit him best to serve his generation wisely in the home, the ward, or the laboratory.

---

[1] Final Report of the Commission on Medical Education. Office of the Director of Study (Dr. Willard Rappleye), 630, West 168th-street, New York. 1932. Pp. 560, including appendix, tabular statement, and index.

The report closes with some brief notes on medical education in six European countries. Dr. WILLARD RAPPLEYE, who, under the designation of director of study has been the organiser of the commission, personally visited certain medical centres in this country, France, Germany, Austria, Sweden, and Denmark, so as to provide the commission with first-hand knowledge of European methods. The summaries of his impressions will be valued by our readers at a time when none of us conceals the feeling that medical education in our own country needs revision in many directions. Some whose cries for the revision of our medical curriculum are most vocal should have before them at least a skeleton of the plan under which the training of medical students in other countries is conducted, so that comparisons to the credit or discredit of our procedure may be instituted. For instance, the place taken by the State and by the universities in the group of countries visited by Dr. RAPPLEYE turns out to be nowhere exactly the same: licensing corporations exist with us which have no exact counterpart abroad; in Germany and Austria medical education is largely developed under the medical faculties of the universities, while with us it has owed its existence to the schools connected with independent hospitals. In this country the holding of a hospital resident appointment is not necessary before the issue of a licence to practise, but in certain American schools the experience of an internship is regarded as part of the basic training. The standards of premedical education and the opportunities for post-graduate expansion present also great variety in the different countries. These things come in for mention in their proper place in an orderly report. If they are often only alluded to, the allusion will be sufficient to remind us that changes made in an arbitrary manner have their risks, for they may jeopardise that entity to which the commission attaches high value, expanding one section—scientific or social—at the expense of other sections equally important. Coördination of effort to obviate duplication and to secure active participation of all in a common undertaking is, in condensed form, the message of a valuable document.

ANNOTATIONS

DEHYDRATION DURING OPERATIONS

SURGEONS have long recognised, more or less empirically, that dehydration plays a considerable part in causing post-operative shock, and rectal or parenteral injections of normal saline solution are widely and successfully used in treating this important complication of major operations. It would be more rational, however, to pay greater attention to the various factors responsible for the negative fluid balance, and in this connexion a paper by F. A. Coller and W. G. Maddock[1] should be welcome. They have analysed the losses of water through all possible channels in a series of operations, most of which were abdominal.

The most important and, to the superficial observer, the least obvious way in which water escapes is through the skin and lungs, which, even in the absence of visible sweating, normally dispose of a large fraction of the fluid which leaves the body. Coller and Maddock find that three-quarters or more of the fluid lost during an operation is accounted for by sensible and insensible perspiration. The excretion of water through the skin may indeed be increased up to as much as ten times the normal rate. This is mainly due to the high environmental temperature of the operating theatre, and to overloading of the patient with blankets. It is greatly augmented if the patient struggles under the anæsthetic. It should also be remembered that overbreathing provoked by ether or nitrous oxide will undoubtedly increase the elimination of water by the lungs. In comparison with perspiration the other factors tending to produce dehydration are relatively insignificant. The loss of blood, though usually greater than the surgeon believes, is not enough to influence fluid balance to any significant extent, except in operations involving extensive dissection of tissue, such as radical amputation of the breast. In such instances capillary oozing is perhaps more to blame than spurting vessels, and the sponges probably absorb, in addition, considerable quantities of interstitial fluid. To the above list two factors might be added which, it is to be hoped, apply to the past rather than the present. The first is pre-operative starvation, during which the body loses large amounts of its fluid reserves, irrespective of the water intake. The second is the over-enthusiastic use of purgatives and enemata before the operation.

There is a practical moral to be gained from the observations of Coller and Maddock. No one would deny the importance of keeping the patient warm while his heat regulating centres are disabled by the anæsthetic. But is it not possible that the modern patient is too lovingly swaddled in wool and hot packs?

THE KING'S FUND DOLL'S HOUSE

IT is difficult to say where the charm lies of a common object, such as a chair, made on a scale which ignores ordinary dimensions; nor is there any good reason, unless psychology can provide one, why a chair in a doll's house should be more generally pleasing than the gigantic throne of an Egyptian god. Perhaps miniatures flatter our self importance. Probably Gulliver preferred being a personage in Lilliput to finding himself a droll but contemptible manikin among the Brobdingnagians. Whatever the reason, small-scale models always seem to enjoy a wide popularity, and King Edward's Hospital Fund for London has chosen a sure way of making new friends in building the miniature hospital which is now on view at 158, New Bond-street.

In this model the scale of ¾ in. to a foot has been faithfully maintained in every detail, from the bricks cleverly marked on the outside to the chromium-plated taps in the bathrooms. The plans of the hospital were prepared by the late Mr. Percy Adams, F.R.I.B.A., and after his death in 1930 the work was carried on by his partner, Mr. Lionel Pearson, F.R.I.B.A. The hospital is made on a T-shaped ground plan, and stands in its own garden; the long-arm of the T houses the wards, and ends in a rounded solarium inside which patients may be seen sun-bathing. Owing to difficulties of packing and transport, there are no separate administrative blocks, nurses' home, or laundry, such as are recognised to be part of the equipment of a modern hospital, but with this limitation the model has been made as complete as possible. The cross-bar of the T contains the matron's quarters (and the matron), the board-room, operating theatres, and kitchens. At the junction of the cross-bar with the long-arm of the T is a square clock-tower accommodating the staircase and a working model of a bed-lift, with patient, trolley-bed, nurse, and liftman all complete. On the top floor of the ward-block is the children's ward, furnished with railed cots and various diminutive toys; the walls are tiled and decorated with nursery rhyme pictures adapted from Thomas Derrick's cartoons. On the floor below is a general ward which is full of new plans for the comfort of the patient. The beds stand in cubicles which can be divided from one another by curtains strung on metal frames; and instead of jutting out into the ward in the time-honoured way, the beds are arranged on the new plan, parallel with the walls, so that the patient need not face the light directly, and, with a little management, can have his feet near the radiator instead of his head. The dual operating theatres are on the same floor as the general ward, but in the cross-bar of the T. The scale-model theatre equipment is complete and delightful; even shadowless lights have been supplied to illuminate the model operating tables, and the latest theatre windows have been fitted into the outer walls. The bottom floor of the main block is devoted to an X ray department, the equipment of which is again a triumph of delicate workmanship.

---

[1] Jour. Amer. Med. Assoc., 1932, xcix., 875.

It is impossible to describe all the details of this fascinating toy—the bathrooms, sink-rooms, private wards, ward kitchens, balconies, kitchen with its elaborate cooking equipment, ambulance yard, or gardens with their sorbo trees, and two inexplicably dejected patients gazing at the fish-pond—but a final word or two must be given to the board-room. This dignified chamber is panelled in sycamore, and floored with teak; the furniture is of walnut, beautifully made, and a heavy hand-made carpet covers the floor. On the walls hang portraits of Florence Nightingale and Lord Lister, also of Lord Moynihan and Lord Dawson, painted by Mr. Alfred Praga, president of the Society of Miniaturists. The King's Fund may justly hope for their hospital the success which so much patient effort and fine craftsmanship deserves.

PATENT DUCTUS ARTERIOSUS

The fact that congenital patency of the ductus arteriosus in its typical form presents characteristic physical signs which are easily recognisable makes it possible to study this form of congenital heart disease with more confidence in the accuracy of the diagnosis than is possible in many other forms of congenital cardiac defect. Dr. D. C. Muir and Dr. J. W. Brown[1] have investigated 20 cases of this condition, 7 males and 13 females, whose ages ranged from 5 to 21. The pathognomonic physical sign, the peculiar continuous "machinery" murmur heard in the second left intercostal space close to the sternum, was present in 12 of the 20 cases, but in one was maximal in the first left interspace. The remaining 8 children presented a harsh systolic murmur maximal in the second left intercostal space, with a definite, accentuated, or reduplicated pulmonary second sound. The presence or accentuation of this sound Muir and Brown regard as important in the differentiation of this condition from that of pulmonary stenosis in which the second sound at the pulmonary area is usually reduced or absent. In no case was any cardiac enlargement detectable clinically, but 7 cases showed a band of dullness in the second and third left intercostal spaces close to the sternum (Gerhardt's dullness). The authors found radiography of considerable value in the confirmation of this abnormality. The pulmonary arc was prominent in antero-posterior radiograms in 16 of the cases, and the conclusion is reached that the radiological features of this condition are definite enough to be of value in its differentiation from other congenital cardiac defects. The striking feature of the symptoms was their rarity. Fifteen of the patients were free from complaints of any kind; 2 complained of præcordial pain, and in 1 it was definitely related to exertion. In 2 cases there was an associated neurosis, largely produced by parental anxiety consequent upon incorrect diagnosis. This illustrates the importance of recognising and differentiating this condition from more crippling cardiac disorders. Transient cyanosis was noticed with infection in 3 cases. One patient presented features of infective endocarditis. This case, together with one of Dr. C. Bruce Perry's, is reported by Dr. Brown elsewhere in our present issue, and may serve as a reminder that every patient with a congenital anomaly of the heart is a potential subject of infective endocarditis. In Muir and Brown's series it was found that the presence of a patent ductus arteriosus affected physical development hardly at all, 6 patients being of average and 9 of over average development, only 5 showing any retardation of growth. As regards incidence, it was found, contrary to the usual teaching, that patent ductus arteriosus was relatively common among congenital cardiac defects. The 20 cases described occurred in a series of 88 cases of congenital heart disease, of which they form 23 per cent. This is a higher incidence than that recorded by Perry,[2] who found 8 cases (6 per cent.) in a series of 121 school-children with congenital heart disease. But if the diagnostic criteria adopted in Muir and Brown's paper were applied to Perry's series the latter would show a higher incidence.

WAR ON THE BLOOD FLUKE

Snails which act as intermediate hosts to blood flukes of man are distributed by and multiply in the irrigation canals of Lower Egypt; these canals are in truth life and death to Egyptians. When in 1925 schemes were put into operation having as final objective the watering of three million acres of the Gezira district of the Sudan, which lies in the angle between the Blue and the White Nile, the problem which presented itself was how the benefits of irrigation could be obtained without its drawbacks in a region which examination of its inhabitants showed to be almost free from schistosomiasis. The risks of introducing it were sufficiently obvious. On the one hand, the drop in temperature in the Gezira in winter was not sufficient, as it is in Egypt, to check the reproduction of snails (nor, it may be added, of the larval stages of the blood flukes developing within them), so that within two years of their opening all the new irrigation canals were, in fact, stocked with bullinus and planorbis snails. On the other hand, immigration of persons whose urine contained living eggs of *Schistosoma hæmatobium* was very great, while the canal banks offered welcome shelter for the purposes of nature, so that miracidia, as they escaped from eggs which reached water, had ready access to their next hosts. As to the extent of the risk from immigrants, the examination of 50,000 at the quarantine stations on the White Nile showed a percentage of urinary bilharziasis varying from 8·4 to 24·4, there being little difference whether the immigrants came from Western or French Sudan in order to earn money enough to buy a wife; or were making a leisurely pilgrimage to Mecca from as far off as West Africa, with intermediate halts to earn their living. Moreover, when irrigation was established, immigration from Egypt set in on a large scale. The risk of widespread infection of the Gezira was, then, great, and the prospect of preventing it unpromising. But the problem was ably met, as is shown in a paper by R. M. Humphreys.[1] After irrigation began, and before the canals became snail-infested, a survey covering over 27,000 inhabitants displayed considerable infection, nearly all in immigrants. All infected residents were compulsorily treated till living eggs were no longer passed, as were infected persons at the quarantine stations before they were allowed to pass into the Gezira. Antimoluscan measures consisted in yearly re-excavation of a third of the 720 miles of canal with drying of the silt, a procedure fatal to these snails; while the rest of the canals were treated by a commercial carbolic fluid sufficient to produce in them a strength of 1 in 20,000, which strength was found to kill all planorbis and bullinus species. To these preventive measures was added propaganda by instruction in schools and by the issue of two pamphlets. One of them showed in simple manner the life history of the fluke, the other contained a copy of a religious decree pronounced by the Grand Mufti, the highest authority in the Sudan of the Mohammedan religion, prohibiting the fouling of water by washing, bathing, or human excrement. The result has been a very great lessening of the amount of infection. A danger threatening tens of thousands of persons has been averted by the foresight of the director of the Sudan Medical Service, Mr. O. F. H. Atkey, by the coöperation he secured with the engineers, and by the conscientiousness with which necessarily uninteresting routine measures have been carried out by the medical officers under his control.

HANS MUCH

The death of Prof. Much can hardly remain unnoticed in this country. When he died in Hamburg a few weeks ago at the age of 52 years he was still director of the Institute of Experimental Therapy at the Eppendorf Hospital whither he was called by Lenhartz in 1907 from Marburg where he was assisting Behring. During this time, as befitted a loyal disciple of Robert Koch, there were few clinical problems connected with tuberculosis which he had not investigated from the serological standpoint, but to the perplexity of his friends and still more of himself his work led him further and further into the wilds of scientific and philosophic doubt. More than in his orthodox studies his memory will survive in the name of an unspecific producer of immunity (omnadin) and in works little short of genius on Buddhism, Egyptian culture, and Low German poetry. Recently the tragic fate of his friend Deycke brought him out of retirement into a merciless attack on the Pasteur Institute and its founder. Soon after reaching Hamburg Much began his work on the acid-fastness of the tubercle bacillus. It had of course then already long been realised that the bacillus was not equally resistant to acid throughout; specimens stained by the Ziehl-Neelsen technique showed a discontinuity of acid-fastness giving the appearance of beaded forms. Much claimed that by means of his special staining there could be demonstrated in pus of tuberculous cold abscesses tubercle bacilli which were entirely non-acid-fast, while still virulent to laboratory animals. He believed there were three states in which the tubercle bacillus occurred, all of them virulent—viz., an acid-fast form, gram-positive non-acid-fast granules, and granular bacilli; and he suggested that the granular forms might represent developmental stages. Later work of other observers suggested that these granules were of a lipoid nature. Nowadays the existence of such a virulent non-acid-fast form of the tubercle bacillus is increasingly doubtful. Most observers believe, with A. S. Griffith, that if the search is sufficiently prolonged the true acid-fast bacilli can generally be found in the pus of cold abscesses which, according to Much, ought not to contain them, whilst direct cultures from such bacilli yield colonies proportionate in number to the scanty acid-fast element seen microscopically. The crux of the question appears to be one of virulence. It may well be true that acid-fastness is associated with the life-cycle of the tubercle bacillus, and is not present to the same degree throughout its whole length. But there are few who hold with Much that a completely non-acid-fast tubercle bacillus can remain virulent. Later on Much turned his attention to the separation of different antigens of the tubercle bacillus on the assumption that the organism had a number of chemically different substances to each of which the human body reacted in a particular way. These so-called partial antigens or "partigens" have been given a very considerable trial without fulfilling what Much hoped from them. They have, however, helped to pave the way for other biochemical investigations of the tubercle bacillus.

STREPTOCOCCI AND RHEUMATIC FEVER

The possible relation between streptococci and rheumatic fever has been investigated from so many angles, with so much apparent confirmation, that some authorities have practically accepted it as proven. The organism has been cultivated from the blood, from the joints, and from the throats of patients—although in this particular respect negative results are perplexingly common. Specific skin tests have been elaborated, and many workers find them convincing. E. W. Todd's[1] striking findings of specific antibodies in the serum of rheumatic patients are recent enough to be well remembered; he found that such persons have a great increase in the antistreptococcal-hæmolysin value of their serum, and his observations are being widely confirmed. New work in America[2] is now advanced as showing that agglutination tests, similar to those employed in typhoid infection, can be applied to rheumatic fever and to various forms of arthritis. Nearly 200 normal persons showed an agglutinating power markedly lower than was present in 300 cases of chronic arthritis and 66 cases of acute rheumatic fever. Only 30 per cent. of normals reacted at dilutions above 1 in 200, whereas nearly 90 per cent. of cases of acute rheumatic fever and 60 per cent.

of chronic cases of arthritis so reacted. Two strains of organisms were used, one "from" rheumatic fever, and the other "from" chronic arthritis. It is not more precisely stated how the strains were isolated; it is of course possible to isolate a streptococcus from any normal person. The authors of the paper say, however, that they do not believe in a specific streptococcus in these diseases; the rheumatic cases reacted with an arthritic strain, and vice versa. In fact, any student of this question will be at a loss to reconcile the divergent claims of investigators who have recognised such specific strains; and Todd's work, already quoted, presents the great difficulty that he estimates the anti-hæmolytic power of serum, although one of the few points common to investigators is that rheumatic fever strains are non-hæmolytic.

From ætiology to therapy is a natural but often fallacious step; and in streptococcal infection imagination has not yet extended beyond serum and vaccine therapy. Two of the same workers in another journal[3] have given the results of their treatment of chronic arthritis by intravenous therapy with vaccines of streptococci. They select this route because they hold that desensitisation in animals can thus be better assured, and because the agglutination titre, which they assume is a measure of immunity, is more readily raised. They claim that 74 per cent. of their cases are definitely improved; moreover, the bactericidal power of their blood was raised. They report unfavourably on the use of subcutaneous vaccines; and of intravenous typhoid vaccine injections, whose employment was sometimes followed by death. They hold that the degree of reaction to treatment is no measure of the success of the method.

The evidence of these authors, who have obviously done a considerable number of tests on animals and on man, must be taken seriously; but the whole question is still unsettled. Although many lines converge on the streptococcus, and no alternative ætiology is so well supported, there are strange incompatibilities. We find one worker obtaining over 50 per cent. of positive blood cultures and another with almost none in 400 cases. H. Warren Crowe and J. C. Small claim results as satisfactory as Clawson and his colleagues, using the very therapeutic measures they condemn. One feels that some essential factor is still awaiting discovery; and that whatever the relation of the streptococcus to rheumatic fever—and relation at least is plausible—it is more complicated than a mere host-parasite relation, such as we find in other pyogenic infections. However, intravenous vaccine therapy, as recommended by these authors, should be without danger; the doses are from 100 million to 800 million; and the organism is stated to be a rheumatic fever strain. Such strains are obtainable in England from the Lister Institute, and clinicians may consider the method worthy of a trial.

AN OPENING FOR CORONERS

UNDER the heading of the Doctor's Day on p. 108 of this issue a coroner remarks that he knows no life which is so interesting or varied as that of a London coroner; and he goes on to make the interesting revelation that as most of the London coroners are nearing the retiring age there will be plenty of vacancies in a few years. He hints too that there is at the present moment a lack of suitable applicants for the post of assistant deputy which may lead in the long run to that of a whole-time coronership. The London coroners are six in number and are appointed by the London County Council. They receive a salary of £1700 and are provided with offices and officers, the latter being police officers told off for the purpose. Each London coroner has an area which includes from three to six boroughs; he has an officer for each borough, and a number of courts, one of which serves as his headquarters. In the county of London all the coroners are whole-time officials, and they are all both doctors and barristers, although only two of them have actually practised at the bar. Outside the county of London the number of whole-time coroners in England and Wales is not great; but there are nine in the Outer Ring, and Birmingham, Manchester, and Liverpool each has its full-time official. In country districts there is not much work for a coroner, and the duties are often discharged by a solicitor who adds them to his other professional duties, and often holds his inquests in the late afternoon or evening after his other work is finished. This cannot be regarded as a permanent arrangement, and we may look forward to a time when the work will be merged into large areas, each with a whole-time coroner possessing both medical and legal knowledge It is not easy to understand how a coroner without medical qualification can cope successfully with the many highly technical medical problems with which he is confronted. The possession of medical knowledge is more important for a coroner than a legal qualification. He must be able to explain to a jury the nature of murder and manslaughter, but he need not struggle with the niceties of the law of evidence, since his inquiry ranges beyond the narrowed limits of an ordinary criminal trial. A reasonably judicial mind in the reception and weighing of evidence, fairness towards persons under suspicion, and patience and courtesy towards witnesses—these are a better equipment than deep legal knowledge.

JUVENILE RHEUMATISM IN GERMANY

A CAREFUL study of 256 cases of juvenile rheumatism, seen at the Leipzig University children's clinic between the years 1923–30, has recently been published by E. Hässler and L. Möller.[1] The clinical features are set out in great detail, the cases being divided into acute rheumatic polyarthritis (110), chorea (81), and endocarditis (65). The first impression gained from a study of these cases is that the mortality-rate is much higher than in this country; 55 children died during the period under observation, giving a rate of approximately 20 per cent. Rheumatic nodules were observed *only* in seven patients, of whom two died, so that this sign, according to English standards a manifestation of severity, was lacking in the vast majority of fatal cases. The next point of interest is the use made of the sedimentation rate. The authors regard this as the most delicate indication of the severity of the rheumatic process, and for the past three years they have carried out the test every fortnight on all their rheumatic patients. In cases where the sedimentation rate, beginning often as high as 100 mm. or more in the first hour (Westergren nomenclature), settles down to normal within a week or so the prognosis is held to be good, while a persistently high rate or exacerbations suggest a smouldering process with acute episodes such as pericarditis. The reaction is also made use of in differential diagnosis, since it is claimed that in polyarthritis due to septic conditions, including post-scarlet fever cases, or in cases with widespread pains in the limbs, as in the early stages of poliomyelitis, the sedimentation rate is normal or only slightly raised. The white blood count is also considered, the absence of gross leucocytosis or shift to the left favouring rheumatism. The occurrence of rheumatism in other members of each family was investigated. There were altogether 523 brothers or sisters in the group, and only 22, or 4·4 per cent., showed any manifestation of rheumatism. Dampness in the homes was seldom found. As regards focal sepsis, 48 per cent. of the children had suffered from tonsillitis at the beginning of their disease, while on admission 57 per cent. showed pathological alterations in the tonsils; 38 per cent. had dental caries.

[1] Jahrb. f. Kinderh., 1932, cxxxvi., 257.

A careful follow-up was made of all but 10 of the patients. Among those who suffered from acute articular rheumatism, Hässler and Möller estimate that two-thirds of the patients completely recovered from their first attack; one-third were left with heart lesions, while 6 per cent. died. Of the cases admitted for a recurrence one-third recovered completely, one-third were left with a damaged heart, and one-third died. The chorea cases did not show the same striking differences between first and subsequent attacks. Just over half recovered completely, most of the others having damaged hearts, while there were six deaths in this series. The group with heart lesions from the onset provide a more complicated analysis which it is impossible to summarise adequately. The conclusion is reached that the fate of rheumatic children is decided usually within the first two years of the onset of symptoms. This seems a more pessimistic outlook than that generally adopted in this country. As regards treatment, tonsillectomy is not favoured, and a method of treating the tonsils with X rays does not seem to have been very successful. Salicylates were found to give variable results and were not without certain drawbacks; pyramidon is recommended as a satisfactory alternative. The opinions expressed on convalescence will depress workers in this country, where many efforts have been made of recent years to secure suitable special convalescent accommodation for rheumatic children. In this series cases kept under careful control in hospital have remained remarkably free from recurrences, while among those sent to special heart homes or ordinary convalescent homes recurrences were relatively common, so that the value of this after-treatment is held to be very doubtful.

HEALTH OF THE ROYAL AIR FORCE FOR 1931[1]

FLYING is becoming safer. In 1931 in the Royal Air Force the ratio of hours flown to accidents resulting in injury or death was greater than in any previous year. The annual report for 1931 records rather more illness this year than in the previous one, attributed to more influenza at home. The main cause of disability in the Force, however, was injury, athletics giving a small increase. The chief causes of invaliding were psychoneurosis (32) and tubercle (25); 20 were invalided for injury. Cerebro-spinal fever caused 10 deaths. When an epidemic threatens, the practice is to space the men out; barrack rooms are warmed; efforts are made to detect carriers, who are isolated for six weeks; and nasal douching and gargling are encouraged in all ranks. Of pulmonary tuberculosis 23 new cases were notified. Fresh cases of venereal disease were fewer this year; they are more frequent abroad than at home. The average number off duty from influenza was 26 men per day; from pharyngitis, 25·6; from tonsillitis, 22·4; and from gonorrhœa, 62·2. Sandfly fever was more prevalent in Iraq than in the previous year; the summer was exceptionally cool, so cases of heat exhaustion were fewer. The hospital at Hinaidi was whitened externally and so cooled, and cold ventilation contrived for the heat-stroke room. "Cold storage" of troops was achieved by arranging a summer camp away northward of Mosul. Chloramine is approved for water sterilisation; Catadyn was tried but a practical method of using it has not yet, it is said, been evolved. Casualties used to be carried in a Neil Robertson stretcher lashed to the outside of an aeroplane; they are now carried inside the fuselage, as if in a marsupial pouch, being emplaned through the bomber's opening of the aeroplane. This arrangement is said to give a much greater peace of mind to the patient. Of officers liable to fly, 95 per cent. were found fit. The chief cause for rejection of recruits was dental defect; of 2039 found fit, 106 had perfect teeth. The information given in the numerous tables dotted through the report are instructive.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED DEC. 31ST, 1932

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 19 (last week 16); scarlet fever, 2033; diphtheria, 825; enteric fever, 27; acute pneumonia (primary or influenzal), 2017; puerperal fever, 26; puerperal pyrexia, 109; cerebro-spinal fever, 41; acute poliomyelitis, 7; encephalitis lethargica, 5; dysentery, 1; ophthalmia neonatorum, 79. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on Jan. 3rd–4th was as follows:—Small-pox, 75 under treatment, 2 under observation (last week 63 and 0 respectively); scarlet fever, 1879; diphtheria, 1719; enteric fever, 12; measles, 259; whooping-cough, 469; puerperal fever, 25 (plus 11 babies); encephalitis lethargica, 229; poliomyelitis, 3; "other diseases," 240. At St. Margaret's Hospital there were 11 babies (plus 6 mothers) with ophthalmia neonatorum.

Deaths.—In 117 great towns, including London, there was no death from small-pox, 1 (0) from enteric fever, 32 (0) from measles, 9 (3) from scarlet fever, 28 (3) from whooping-cough, 44 (19) from diphtheria, 44 (8) from diarrhœa and enteritis under two years, and 303 (25) from influenza. The figures in parentheses are those for London itself.

The fatal case of enteric fever occurred at Brighton. Measles caused 8 deaths at Birmingham, 7 at Liverpool, 4 at Leicester. Three deaths from whooping-cough were reported from Liverpool and from Sheffield. The fatal cases of influenza were reported from 61 great towns, the largest number of deaths being 92 at Birmingham, 24 at Newcastle-on-Tyne, 23 at Sunderland, 8 at Southampton, 7 at Portsmouth, 6 each at Leeds, West Hartlepool, and Walsall. In the same week Glasgow reported 86 deaths from influenza and 10 from whooping-cough.

The number of stillbirths notified during the week was 253 (corresponding to a rate of 49 per 1000 total births), including 38 in London.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.—At a dinner meeting of this society to be held at the Hotel Rembrandt, Brompton-road, London, S.W., to-day, Friday, Jan. 13th, at 7.15 for 7.30 P.M., Mr. Timbrell Fisher will open a discussion on Arthritis, and Mr. Alan Todd will speak on the Orthopædic Treatment of the disease.

SPECIAL ARTICLES

TUBERCULOSIS ON THE WITWATERSRAND

THE EFFECT OF MINE EMPLOYMENT UPON THE NATIVE WORKER

DURING 1925 the Transvaal Chamber of Mines had under consideration the advisability of instituting an intensive campaign against tuberculosis on the mines within its organisation. Preliminary investigation very soon proved that the problem could not be adequately investigated as a purely local one, confined merely to the native mine labourers employed temporarily upon the Witwatersrand. Not only was it essential to extend the field of inquiry to the native territories from which the labour force is recruited, but in addition many unanticipated lines of investigation proved inevitable. This led, in 1926, to the formation of a Tuberculosis Research Committee, composed, under the chairmanship of Sir Spencer Lister, of representatives of the Union Government, the South African Institute for Medical Research, and the Transvaal Chamber of Mines. The main objects of inquiry were twofold :—

(1) The extension of knowledge concerning tuberculosis as it occurs in South Africa, and more particularly in its relation to the native races : and

(2) The diminution of the morbidity and mortality from tuberculosis amongst the European and native miners in South Africa, most of whom are employed in the gold-mining industry on the Rand.

Vital statistics concerning the native populations were non-existent, the extent of their tuberculisation was unknown, the fate of those who, having developed tuberculosis during their employment on the mines, were repatriated to their distant homes was but surmised ; and of the part that these natives played in spreading the infection amongst their families and others in the kraals there was no evidence. It is obvious that the committee were faced with a very difficult but important problem of industrial and public health. The result of the many lines of investigation they instigated are coördinated in a report issued as one of the publications of the South African Institute for Medical Research.[1] Interspersed in the report is a valuable running commentary by Prof. Lyle Cummins on the evidence collected and the conclusions reached.

TUBERCULOSIS IN VIRGIN SOIL

The attention of the committee was first devoted to general considerations upon tuberculosis in virgin soil, and they summarise the work of previous investigators to establish the point that members of isolated communities exhibit a marked susceptibility to tuberculosis when brought into contact with infection, and that although the infection may be fairly well tolerated under natural or tribal conditions, it is likely to lead to fatal results when accompanied by a change in occupation, food, housing, and mode of life. A historical survey shows that little or nothing is known as to the existence of the disease amongst the Bantu tribes prior to their contact with the white races, but that there is considerable reason to believe that it must have been very rare amongst them under their primitive conditions. However, the infection had already taken a firm hold amongst them in the first half of the nineteenth century, at least in those places where the existence of military, trading, missionary, and other centres ensured close touch between Europeans and natives, and provided efficient means of recognising its existence. On the other hand, Maynard's observations in 1912 on tuberculisation (by means of Calmette's ophthalmo-reaction) suggested strongly that a large proportion of natives from Nyassa and Mozambique arrived at the Rand free from any considerable contact with tuberculosis prior to their engagement.

TUBERCULOSIS AMONG RECRUITS

This result is not supported by the large-scale investigations of the present committee. Of nearly 60,000 natives applying for engagement at the mines, 72 per cent. were found to give a positive response to a single intradermal test with one-tenth of 1 c.cm. of 1/5000 old tuberculin. Repeated tests with stronger solutions would, it is believed, probably show that 90 per cent. of the boys applying for engagement are bringing their tuberculosis with them to the extent of giving a positive response to the tuberculin test. In addition, extensive investigation in the native territories showed a high degree of tuberculisation as judged by the tuberculin test, and it is stated that the incidence of tuberculosis is higher in mine boys coming from the least tuberculised area. This suggests that the tuberculosis of the native labourers is not necessarily acquired on the mines ab initio, but that the disease may develop either through super-infection or through stress of work or other circumstances. Confirmatory evidence on this point is that amongst new recruits, with no evidence of previous mining service, dying from conditions other than tuberculosis within a few days of their arrival, there have been found a certain number of cases with definite tuberculous lesions, clear proof that some natives do arrive already infected. To be quite certain that these recruits have not had previous service at the mines is, however, admitted to be very difficult.

RESISTANCE TO INFECTION

Observation of the tuberculin-tested boys, for periods up to two and a half years after the test, showed, contrary to the evidence cited above relative to area of recruitment, that those yielding a positive reaction to this test were more likely to develop a recognisable tuberculosis than those yielding no response, the ratio of the incidence being approximately two to one. In addition, the possession of tuberculo-allergy was not associated to any useful extent with the ability to modify an after-coming tuberculosis. On the whole, therefore, it appears evident that these natives, infected during their childhood or adolescence in the kraals where tuberculosis is, according to the available evidence, now endemic, have, in many cases, developed only sufficient resistance to keep their initial lesions latent under the easy conditions of tribal life. For the new and strenuous conditions of life and work on the mines the resistance of at least a certain proportion of them is quite insufficient. In their search for causation the committee has scrutinised these conditions very closely. On recruitment there is the long and arduous journey from the territories to the Rand, the change from the warm levels of the African coast to a climate which is, at least in the winter months, very cold, dry, and dusty. Further investigation, the committee recommends, should be made into the conditions of transport. Apart from the minority that contracts or develops bacterial disease, the natives appear to benefit in health by their life in the mine compounds, for the majority gain in weight during their period of service.

---

[1] Publications of the South African Institute for Medical Research, No. 30, vol. v. Tuberculosis in South African Natives, with special references to the disease amongst the mine labourers on the Witwatersrand. 1932. Pp. 429.

PROTECTIVE MEASURES

Improvements could be introduced, the committee believes, in the direction of having fewer occupants per room and better separation of the individual bunks in each room. At present, in Prof. Lyle Cummins's opinion, the conditions of housing appear calculated to facilitate the spread of influenza and other respiratory infections. The diet supplied to the native workers could be improved by the additions of vitamins A and D, in both of which it is somewhat deficient. Serious difficulties in the way of this reform lie in the conservative customs and habits of the natives and in the cost—an extra penny a day per native involves an additional expenditure of £300,000 per annum. Another problem to be considered in relation to diet is the native custom of taking food only twice daily, shortly after rising and again in the late afternoon. Such a habit may not be detrimental to health under the relatively easy life in the kraals, but it is another matter when the native is carrying out eight hours of continuous muscular work (with an average of 10½ hours in all underground), to all intents and purposes on an empty stomach. This arrangement is obviously unsatisfactory, and, the committee concludes, should be capable of being improved with advantage to all concerned. A technical problem of importance is involved in the protection of the workers, during their return from hard work in the great heat of the deep levels, from sudden changes in air temperatures and velocities, while there should be a gradual "acclimatisation" of new recruits to their work in deep mining. On all deep-level mines there does now exist a system of "entering" new boys through a series of graduated tasks, and the committee recommends that this system should be strictly adhered to and, if possible, improved.

MEDICAL CARE OF REPATRIATED NATIVES

Such are some of the conditions of life at the mines which the committee has passed under review. In addition, they point out that since the endemic tuberculosis of the native territories constitutes a danger to the mines, and the tuberculosis cases repatriated from the mines involves a danger to the territories, any comprehensive anti-tuberculosis policy must include measures not only on the Witwatersrand but also in the native territories. At present there is no organised medical service in the latter, and the majority of the subjects of the Union Government, the committee states, have no hope of medical aid beyond what they may obtain from their own witch-doctors. The absence of reliable vital statistics seriously impedes the planning of any organised campaign against tuberculosis. Investigations carried out in the territories show that faulty conditions of life and diet before coming to the mines may predispose to a danger of breakdown in health. The committee urges the appointment by the industry of a medical officer to travel in the native territories, and to be specially charged with the duty of dealing with tuberculosis among repatriated mine natives and in areas in which intensive recruiting takes place. At present a sample inquiry by Dr. Peter Allan suggests that of repatriated boys, at least 60 per cent. are dead within two years (30 per cent. of the cases were untraced, and possibly many of these had died). According to the rather slender evidence available familial spread from these repatriated cases was not a very common phenomenon, perhaps owing to the rapid termination by death. All the evidence, clinical, pathological, and statistical, shows that the new mine natives run the greatest risk, and that among them the disease is of a very acute and severe type (taken over two years' duration the fatality rate is estimated to be 70 per cent.). The "long-service" natives learn to tolerate tuberculosis to a greater extent, and may, perhaps, therefore serve as a reservoir of infection.

INCIDENCE OF TUBERCULOSIS ON THE RAND

An accurate measure of the actual incidence of tuberculosis on the Rand is an exceedingly difficult thing to attain. The labour turnover approximates, on the gold mines, 100 per cent.; the age-distribution and length of service of the workers are only approximately known. The workers are selected under a system of rigorous initial medical examinations; convalescent natives whom the mine medical officers regard as unfit for further work are repatriated. It is essential to know whether the measure is really inclusive of all tuberculosis or only of tuberculosis "under the Miners' Phthisis Act"—i.e., cases expectorating tubercle bacilli, or with closed tuberculosis of the lungs or respiratory organs to such a degree as seriously to impair working capacity and render prohibition of working underground advisable in the interests of health. These factors inevitably throw doubt upon the conclusion reached in the statistical section of the report that "many European countries and countries inhabited by European stocks have a prevalence rate of tuberculosis no lower than that obtaining among our mine natives for the same age-group." In fact, in an earlier section (p. 56) the committee concludes "that an exact weighing of the morbidity and mortality experience . . . . to enable comparison with similar experience in more settled industrial populations is impossible, and even a close approximation can hardly be arrived at on the data at present available." Further statistical returns are required (though comparability with European countries may never be possible), and for this purpose, and to ensure continuity of policy of investigations and application of suitable anti-tuberculosis measures on the mines, the committee recommends to the Chamber of Mines that a Standing Advisory Health Committee be appointed and maintained by it.

The report is a most valuable and comprehensive survey of an important problem—regarded from the economic aspect alone it costs the industry something like a million pounds annually in compensation—and the findings of the committee should certainly be followed up.

CITY OF DUBLIN SKIN AND CANCER HOSPITAL.—At the annual meeting it was stated that, in addition to the money lost directly by exclusion from the sweepstakes, the hospital has lost indirectly part of its voluntary incomes "as the inevitable tendency of the publication of the enormous amounts which have been made available for the participating hospitals has been to dry up the wells of charity." During the year there were 276 in-patients, all suffering from cancer or lupus: the out-patient department is chiefly concerned with skin diseases. The medical report expresses satisfaction with the results of the fluorescein X ray treatment and the treatment of cancer of the uterus by the combined methods of radium and deep X rays.

CONFERENCE OF EDUCATIONAL ASSOCIATIONS

IN the course of this conference which was held at University College, London, from Jan. 2nd to 9th, the Child Guidance Council arranged a lecture on

Educational Problems in a Child Guidance Clinic

Dr. WILLIAM MOODIE said that educational knowledge or teaching experience was essential for anyone who was trying to elucidate a child's problems. At the child guidance clinic relatively few children came up with the complaint of "backwardness," but on investigation 65 per cent. of all the patients showed some discrepancy between their capacities and their performance. Backwardness did not mean mental defect; a backward child was one who was not doing all he might. One great problem was the child with an intelligence quotient of 80–85 who was neither normal nor defective. The adult's attitude and the child's own attitude towards his performance were extremely important factors. Many of these children and their parents were quite content, but trouble arose when the parent tried to thrust forward a child of subnormal capacity, or when the child needed achievement for its own satisfaction. One of the advantages of the child guidance clinic was that it obtained its information about the child indirectly. The doctor who examined the child was under the disadvantage that information about the child's mental attitudes could only be obtained while the child was exercising them. The child would "give himself away" in the test situations provided by the psychological expert. Many children showed backwardness in school subjects, although intelligent enough in other ways. These displayed on examination a fundamental difficulty in discriminating form and position. Their trouble was not "word blindness" but blindness to something more basal. About the age of 11 or 12 the faculty of appreciating the symbol developed and the difficulty disappeared, but trouble then arose because at that age the child was expected to use his ability and was no longer being taught. Specific difficulties with circumscribed subjects were almost always emotional. The power of abstract thinking increased enormously round about adolescence, and emotional difficulties at that age might retard or throw back educational performance. The chief falling-off was usually in calculation.

Children were sometimes kept from school by their doctors on the pretext that they must "rest their brains," and they never got over the loss. It would be as sensible to say: "He is growing too fast; do not give him enough to eat." Later opportunities might enable the child to make up for the educational chances missed, but nothing could make up for the social education he had lost during the period at home. Children were often said to be "lazy," but was there any child who failed and liked it, or "could do better if he liked"?

In many cases, said Dr. Moodie, physical difficulties were responsible for educational trouble. Sense disturbances, such as partial blindness and partial deafness, were handicaps to education, and astoundingly difficult to identify. Many children, both defective and normal, were inattentive. These children were often fatigued; teachers realised the importance of fatigue better than doctors did. Children might live and sleep in noisy surroundings so that their sleep was always disturbed: sound, light, and vibration influences were continually assaulting them, even though they got their normal hours of sleep. Malnutrition might be the cause of educational difficulties, or the child might suffer from wrongful feeding, but on the whole it was astonishing how well London children were fed. The idea of sepsis as a cause of disorders in children was overdone; the tonsils had a useful function. The manifestations of nervous conditions, such as chorea, were often emotionally determined. Epilepsy was responsible for many difficulties, and was often not recognised.

The question must be faced whether or not society was going all wrong in the treatment of its young. All difficulties were ascribed, more or less, to repression, and punishment was said to be useless. Most of the problems of child guidance would never arise if the children had been handled differently in earlier days. The only real problem child was the child who failed to be guided as other normal children had been guided. The swing away from advice, guidance, and discipline was wrong. Probation was a temporising and hoping for the best; it was not constructive. Parents to-day did not know what to believe or to do. Educationalists had a chance of doing something; they could sit back and think, for they had not the emotional problems towards the children that parents had. A little more hard handling was indicated. Child guidance had learned enough by now to distinguish between punishment and corporal punishment, between freedom and licence, between repression and discipline. Part of the educational campaign of child guidance and educational authorities was to stress to parents their responsibility. Coöperation between teacher and parent was of the greatest importance, and more and better classification was needed, especially temperamental classification.

The Place of Punishment in Child-training

Dr. F. C. SHRUBSALL delivered a lecture to the Child Study Society on this subject. The psychiatrist, he said, might see cases whose mental trouble could be traced back to the effects of punishment, but those who dealt with delinquents saw another side of the picture: people who were brought almost to the foot of the scaffold as a result of not having the right punishment at the right time. Both points of view were right, and a balance between them must be found. In considering punishment the idea of vengeance must be excluded and the formative aspects of punishment must be considered mainly, even the reformative aspect taking second place. All parents must feel willing to join in the general confession that they had left undone those things they ought to have done, and done those things they ought not to have done. The young child, like the animal, directed its life on the pleasure-pain principle, and learnt by example far more than by precept. In primitive communities there was no didactic punishment, but unruly children doubtless met with rough handling from their outraged relatives, and their ability to stand hardship was severely tested at the period of initiation. In tribes of slightly higher culture whipping by a "devil" was supposed to free the offender from the effects of his misconduct. In one initiation ceremony the boy received three severe thrashings: the first to teach him to obey the tribe, the second to teach him to obey his father, and the third to teach him in no circumstances whatever to obey his mother. The establishment and persistence of corporal punishment in British schools was due to the two great literary influences dominant in the period of their foundation: the Greek and the Hebrew. In Sparta and Greece, boys over 7 went to boarding-school, where there was a well-developed prefectorial system, the seniors having the right to whip the juniors. In the Bible there were various passages suggesting that whipping was desirable, although when the original Hebrew was considered it was quite clear that the basic idea was one of training for the child's own good. The disappearance of corporal punishment was no doubt largely due to the greater sense of companionship between children and adults. Even the most devoted child-lover, however, was apt to admit the necessity for punishing a child that insisted on running into the road, and the argument applied equally well to other dangerous practices. A training which allowed the child to do as it liked in the hope that it would eventually choose the best would not fit it for life in the world to-day. There was probably no child psychologist in existence who, having a child of his or her own, had never spanked it.

It was difficult, he said, to see why dermal pain was regarded as so unsuitable a method of correction. It was through dermal stimuli that the young thing distinguished between the self and the non-self, and learned to avoid harmful objects. The burnt child feared the fire, and the relation between the action in touching the fire and the painful result was immediate. Only when the result was immediate could the necessary association be set up. A delayed punishment or a subsequent deprivation was to the young child either unnoticed or else just one of those inexplicable things that were constantly happening. An immediate smack set up an association which would be remembered. Punishment must be immediate and should be given in anger. The emotion of anger was quite well understood by the child, and had no ill-effects, but reasoning with it and giving it time for reflection might alarm it considerably by threatening its sense of home security. The habit of absolute obedience must be established before school age, but rebellion should be deflected rather than punished, and punishment should not be given for honest experiments. The child must learn the difference between the command that had to be obeyed and the mere suggestion; it was not fair to use the same tone for both.

The alternatives to physical pain were unsatisfactory. A tongue-lashing might inflict far more damage on the nervous system than any number of blows. At the school age it was important to reserve punishment for real offences. The important offence at this age was the offence against personal control. Nobody took it very seriously if a small boy stole apples from an orchard in the country, and the farmer's vengeance was all part of the game, but when the town child had to steal his apples from crates, a great deal more fuss was aroused. One very important thing was that the child should never believe himself immune from corporal punishment, even if that punishment was never applied.

Risks of Competitive Games and Sports

At a meeting of the Medical Officers of Schools Association the chair was taken by Dr. G. E. FRIEND, and Dr. R. COVE-SMITH opened a discussion on this subject. Sports and games, he said, were not physical exercises only but also of mental and moral value; body, mind, and spirit constituted the tripod on which the human being rested, and if one were longer or shorter than the others the whole individual would be unbalanced. Men should be trained like dancers to keep step with the rhythms of life. In practice there was a great tendency for school games to become a tyranny instead of a creative outlet and an opportunity for the liberal education of the body. Physical training was far too often in the hands of people with little or no knowledge of anatomy or physiology. The organised games of school life could profitably be replaced by fencing, camping, scoutcraft, spontaneous play, morris-dancing, and swimming. The competitive character of games tended to take away a great deal of the fun, and they became orgies of record-breaking and cup-hunting. Moreover, the competitive spirit directly tilted against the production of a satisfactory citizen, whose keyword should be "coöperation," and added an emotional to a physical strain. Whereas physical fatigue promoted sleep and recuperation, emotional fatigue prevented sleep. Further, the boy who was good at games got overtrained, and the others were neglected. It was undesirable in every way for the young child to be competitive.

Dr. J. LAMBERT said that the competitive spirit was essential in the development of character. The non-competitive game ceased to attract the boy as he grew older, and he found the competitive element a welcome break in the monotony of drill. The child under 9 was much less liable to serious injury; his bones and muscles were more elastic and he fell more lightly; also he had less determination to win, and would not run himself out in a race. Dr. Lambert produced statistics from his own experience to show the comparative rarity of injury in preparatory schools, but pointed out that when a special inquiry had been made recently only six fatal cases could be found in all the public schools in the country. Two had occurred in football, two in cricket, one in diving, and one in high jumping. The worst fractures he had seen had been due to inattention in the field at cricket. The danger in school games lay in the possibility of a tyranny being set up by a too-enthusiastic master or captain, and in unequal grouping of boys in football and boxing. The school doctor could see that this did not happen, and could also see that the boy who had a heart damaged by some infection did not over-exercise. The healthy heart was not likely to be hurt by exercise, and its reserve limit was not reached even if the boy ran himself out. The type of boy who was most likely to suffer was the older, all-round athlete who was expected to be consistently good, and who regarded an afternoon off as an unforgivable sin; he was living keyed-up all day and every day. Dr. Lambert concluded that the dissociation of the competitive spirit from games would be a retrograde step.

The CHAIRMAN agreed with Dr. Lambert on the value of the competitive spirit, but admitted that it wanted careful watching. In his experience, casualties were 50 per cent. more numerous in house games and cup-ties than in friendly games. It was very difficult to damage the heart of a schoolboy who had adequate medical supervision.

Mr. H. G. SWEENY said that the competitive spirit had been implanted by nature and could not be eliminated. Savages did not progress because they were devoted to coöperation and had no competition. The only evil was excess.

Mr. R. E. ROPER pleaded for the transfer of school sports to the autumn term, pointing out the five-fold strain upon the child of working for certificate examinations, working for prizes, working for school examinations, training for school sports, and training for swimming sports. He also pointed out that small children often preferred to play a game their own way, weaving a rich phantasy around it.

THE HOUSING PROBLEM

WITHIN the last few years the housing problem has become somewhat complicated. The new statutes are causing some confusion. The cry for the removal of slums has somewhat blanketed the schemes for the provision of houses. Under one statute the removal of slums must proceed step by step with the provision of houses under grants calculated on the units housed. The local authorities have shown a considerable readiness to take up this compound scheme. Meantime, however, there is pressure with other methods. Private enterprise, as was to be expected, is asserting its claims. It is alleged that the local authority houses cannot be built to be let at sufficiently low rates. It remains to be seen whether private enterprise, however ingenious the financial arrangements, will be able to do any better. Meanwhile, compared with the earlier output of houses, the numbers have fallen off considerably. Nevertheless, the annual average from 1919 onwards has kept round about 12,000 to 13,000 a year. It is quite certain that more houses are still needed; but there will be a mixed fight in the methods of providing them. The recent change in the rate of interest has stirred up the building societies, and it is supposed that the new financial schemes will end in houses of cheaper rents. Cheaper rents are, of course, a necessity; but I am sceptical of the new methods of securing them.

WORK OF A MENTAL HOSPITAL

In the annual report of the Stirling Mental Hospital it is stated that the general quietness and orderliness in the lives of the patients is largely due to the successful efforts made in finding suitable occupations for them and so maintaining an interest in their surroundings. The methods followed have long been familiar in the Bangour Mental Hospital of the city of Edinburgh. The superintendent finds the predominant interest of the patient and sets him to appropriate work. The difference between patients managed on those lines and by the old methods of confinement can be realised only by direct inspection. Of 150 patients discharged, 98 were discharged recovered, giving a recovery-rate, calculated on the number of admission, of 37·1 for both sexes; 62 patients had recovered within six months of admission and 22 after twelve months. One man was discharged recovered who had been resident in the hospital for seven years.

A complaint made is that the institutions primarily for the treatment of mental ailments should have their hospital departments crowded out with senile cases. These could be satisfactorily cared for in some more suitable way, and it seems unfair that those old people should be certified as insane and detained under a sheriff's warrant. Most of them could be readily dealt with by utilising some of the spare accommodation in the poor-houses throughout the country, the only additional requirement being a few nurses to look after them. This problem, no doubt, will ultimately find a solution as the consolidation of institutions under the new authorities proceeds.

EDINBURGH MUNICIPAL HOSPITALS

I learn that the problem of the municipal provision of hospitals is in process of being solved satisfactorily. The difficulties of medical staffing of the hospitals seem to have been got over.

MEDICAL MEN AND THE IRISH ELECTIONS

ALTHOUGH the list of candidates is not complete at the moment of writing, it looks as if medical men would be more prominent in the elections now to take place—and, one may hope, in the new Dáil—than they have in the past. For the city of Dublin there were in the last Dáil three medical deputies—Mr. T. Hennessy and Dr. Myles Keogh, both Cumann-na-n Gaedheal, and Dr. J. B. Lynch, Fianna Fail. All are again going forward. Sir James Craig is certain of re-election unopposed for Dublin University. Two members of Mr. de Valera's Government, Dr. James Ryan, Minister for Agriculture, and Dr. C. Ward, Parliamentary Secretary to the Minister for Local Government and Public Health, have again been selected as candidates for their respective constituencies, County Wexford and County Monaghan. Dr. R. E. Davitt is to contest Meath as a supporter of Mr. Cosgrave. Dr. Vincent White is again a candidate for Waterford, and Dr. Edward Dundon has been selected as a candidate for Kilkenny and Carlow, both in the Cumann-na-nGaedheal interest. On the same side Dr. T. F. O'Higgins and Dr. P. Doyle are candidates in Leix and Offaly (Queen's and King's Counties).

AUSTRALASIA

(FROM OUR OWN CORRESPONDENT)

POST-OPERATIVE TETANUS

TETANUS developed in two cases recently operated on consecutively at the Wollongong Hospital, New South Wales. Both patients, who lived in adjoining houses, were operated on for removal of the appendix by the same surgeon, and both died. An inquest was held, and after a thorough investigation of the catgut used, the coroner held that it was responsible for the tetanus. The catgut was stated to have been of German origin.

Within the past week a further case of post-operative tetanus has developed in South Sydney Hospital, Sydney. The catgut used on this occasion was the same as that used at Wollongong. The Minister for Public Health, on the advice of the government microbiologist, has sent a communication to all hospitals in New South Wales, stating the brand of the catgut used. He suggests that all available supplies of this catgut should be discarded and further, that for the future only catgut of British origin should be employed.

POST-GRADUATE TEACHING

Post-graduate work in New South Wales was carried out in a desultory manner until several years ago, when the New South Wales branch of the British Medical Association undertook to put the organisation of post-graduate work on a more satisfactory footing, by appointing a committee to develop it. The branch has now disbanded its own committee, and has founded a permanent post-graduate committee, on similar lines to the committee which for some years has carried out very satisfactory programmes of post-graduate work in Melbourne. The new New South Wales committee, which is representative of Sydney University and the eight larger metropolitan hospitals, has already begun work.

AIR TRANSPORT OF PATIENTS

Transport of the sick by aeroplane is becoming a regular feature of the Australian outback, and in Queensland a regular aeroplane medical service has long been in operation. It is almost a common thing for a specialist to travel 400 or 500 miles by aeroplane, and recently a Sydney doctor travelled 1400 miles by aeroplane to Mount Isa to attend a sick woman. The longest of these journeys was probably in 1930, when a Quantas, Limited, aeroplane was engaged by the Australian Inland Mission to bring a patient from Port Darwin to Sydney, a distance of nearly 2000 miles.

MEDICINE AND THE LAW

Rejection of Finger-print Identification

SCIENTIFIC research may equip Scotland Yard with methods for the detection and conviction of a criminal, but a British jury cannot be compelled to accept them. The system of identification by finger-prints is an example. The work of Dr. Henry Faulds, Sir Francis Galton, and Sir William Herschel, established its value; Sir Edward Henry thoroughly tested its applicability for criminological purposes; yet the application remains haphazard. However useful to the police in the narrowing of the field of detective investigation, the system is still an uncertain weapon for a prosecution to rely upon exclusively. In R. *v.* Chadwick, 25 years ago, where it was a question of convicting a burglar by the evidence of finger-prints left upon a champagne bottle, the judge warned a Birmingham jury that it would not be safe to accept such evidence as a basis for conviction; the jury nevertheless found the accused guilty. A converse situation was reported lately from Brighton quarter sessions. A Brighton office had been broken into; pieces of glass found in a waste-paper basket in the office were carefully taken out by a charwoman, wrapped in a duster, and given to the police. A Scotland Yard detective-inspector stated in the witness-box that he was positive the finger-prints on the glass were those of the accused; he had never known the impressions of two persons' finger-prints to be alike. The Recorder explained to the jury the significance of this identification but the jury rejected it. Scientific research may be decisive as to the finger-print system; popular opinion may still disregard it.

On Monday last, the centenary of Herschel's birth, the *Times* published an interesting account of the official development of the finger-print system, written by Sir John Moylan, who explains the significance of Mr. Battley's new method of using single finger-prints. The article may be said, with all respect to the Brighton court, to carry conviction.

Identification from Photographs

If judges or juries look with suspicion upon the unfamiliar, they may go to the other extreme where the operation of some scientific process is well established. Thus photography is readily accepted in the law courts in spite of its technical limitations (in the matter, for instance, of perspective) and in spite of the fact that the individual use of its results may be fallacious. The police force preserves photographic records of criminals and employs them where the author of a crime is undiscovered. Suppose that a burglary has been committed and that the butler, who says he saw a man running away from the house, is shown a series of photographs by the police and is asked if he can pick out the man he saw. Suppose that, after prolonged study of the photographs of A, B, C, and D, the butler says that the photograph of A is very like the wanted man. If the butler afterwards picks out A at an identification parade or identifies him in the witness-box at the trial, there is a real danger that he will be identifying A from his recollection of the photograph of A rather than from his recollection of the man seen running away from the house. This point was taken last year in the Court of Criminal Appeal in R. *v.* Hinds, a case where the main issue was that of identity. The appellant's counsel asked the Court to upset the conviction on the ground that the judge at trial had not specially warned the jury that the value of identification by a witness might be lessened by the fact that the witness had previously picked out the photograph of the accused from a series of photographs displayed to him by the police. The Court of Criminal Appeal, however, dismissed the appeal and held that no such warning was necessary.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

Surg. Capt. T. W. Jeffery, retd., to be Medical Officer for the R.N. Armament Depôt, Lodge Hill and Upnor, vice the late Surg. Capt. W. G. K. Barnes, and Surg. Capt. J. J. H. Rooney, retd., to be Medical Officer for the R.N. Torpedo Factory, Greenock, and Admiralty Surgeon and Agent for Greenock, vice Surg. Comdr. F. D. Lamley.

Surg. Lt. E. R. P. Williams to be Surg. Lt.-Comdr.

Surg. Lt. (D) H. E. Rose to be Surg. Lt.-Comdr. (D).

ROYAL NAVAL VOLUNTEER RESERVE

Surg. Capt. R. J. Willan, K.H.S., is placed on the retd. list.

Surg. Sub-Lt. G. H. C. R. Critten, to *Royal Oak*.

ROYAL ARMY MEDICAL CORPS

Majs. M. J. Williamson and A. D. Stirling to be Bt. Lt.-Cols.

Capt. S. G. M. Lynch, from R.A.M.C., T.A., to be Lt. (on prob.).

Lt. N. H. Lindsay to be Capt. (prov.).

Lt. (on prob.) H. C. M. Walton is restd. to the estabt.

Lt. W. B. Williams and Lt. (on prob.) M. Fallon resign their commns.

TERRITORIAL ARMY

Maj. A. S. Hebblethwaite to be Bt. Lt.-Col.

Capt. J. E. McCartney (late R.A.M.C.). to be Capt.

J. H. Taylor (late Cadet Lce.-Corpl. Glasgow Univ. Contgt., Sen. Div., O.T.C.) to be Lt.

A. G. W. Whitfield (late Cadet Corpl. Wellingborough Sch. Contgt., Jun. Div.. O.T.C.) to be Lt.

INDIAN MEDICAL SERVICE

Lt.-Col. M. R. C. MacWatters retires.

COLONIAL MEDICAL SERVICES

Dr. H. S. Lawrence has been appointed Medical Officer of Health, Jamaica, and Dr. T. W. Ware has been promoted Health Officer, Hong-Kong.

Surg. Capt. J. B. Ronaldson, R.N.V.R., has been appointed an Honorary Physician to the King in place of Surg. Capt. R. J. Willan, R.N.V.R., who has retired.

KING EDWARD'S HOSPITAL FUND FOR LONDON.—Amongst the latest contributions to this fund is the sum of £1000, being the annual subscription of H.M. the King.

AN INVESTIGATION OF THE MENOPAUSE IN ONE THOUSAND WOMEN

IN October, 1926, a subcommittee was appointed by the Council of the Medical Women's Federation *for the purpose of investigating, from the clinical* aspect, phenomena associated with the menopause. The data on which this report, which is here published in full, is based were collected on 1220 questionnaire forms, each of which was filled in by a medical woman as the result of a personal interview with the individual from whom the information was obtained. The inquiry referred to women in whom five years or more had elapsed since the cessation of the menses. Their ages, when interviewed, varied from 29 to 91.

The Report

In order that the source of the data should include women of normal health and in all conditions of life, the subjects of the questionnaire were, as far as possible, other than patients. They included married and single women of various social status, leading an ordinary home life, women engaged in or retired from the various professions, intellectual and manual occupations and domestic work. They lived in cities, industrial areas, and rural districts in various parts of England and Scotland. Many of them were in public assistance institutions in different parts of the country. Apart from the advantage of the ease with which large numbers could be thus approached, it was thought that they would represent a good average of health in view of the fact that their presence in these institutions was determined by matters of finance, or accident, or death of relations, rather than by their own health.

Our inquiry was spread over a period of five years, and when completed the 1220 questionnaire forms were sent to a statistician, Mr. W. T. Russell, who compiled many tables of figures and wrote a full *analytical report, which is quoted freely in the* following paragraphs. We are greatly indebted to Mr. Russell for this work, without which the real values of our material could not have been obtained. He found 1197 of the schedules sufficiently complete *for use in the investigation; 835 of these referred* to married, and 362 to single women. Here, in order to reduce the quotation of figures to a minimum, percentages only are given and they are, as far as possible, incorporated in the text, which deals with *the main points of general interest emerging from* the investigation. These are considered under the following headings:—

1. The proportion of women free from menopausal symptoms.
2. The frequency of t[illegible]oms: *flushing*, hæmorrhage, giddiness, [illegible]stability, pain in breasts, "rheumatic" [illegible] thyroid gland, obesity.
3. Incapacity due to the menopause.
4. Age of onset and cessation of the menses.
5. *The effect of the following factors on the prevalence of* symptoms and age at the menopause: age of onset of the catamenia, miscarriage and childbearing, menstrual history, previous health.
6. Comparison of the points mentioned above in married and unmarried women.

THE PROPORTION OF WOMEN FREE FROM MENOPAUSAL SYMPTOMS

Of the total number of women questioned, 15·8 per cent. stated that they had passed through the menopause without any symptoms. The frequency in the case of single women was 20·4 per cent. and of married women 13·8 per cent., a difference of 6·6 per cent., which, when tested against the usual criteria for statistical significance is of importance and is not due to chance.

SYMPTOMS ASSOCIATED WITH THE MENOPAUSE

(*a*) *Flushing.*—Of all the symptoms associated with the menopause, flushing was the most frequent. It occurred in 62·3 per cent. of the total number, and in 4·8 per cent. of these cases it was the only symptom noticed. The intensity of the flushing varied very much. In some it was barely perceptible, others complained of severe "heats" accompanied by sweating many times during the day and night. Many of the women regarded the inconvenience of flushing a trivial matter compared with the discomfort they had suffered from blushing in their youth. Others considered it the most serious and weakening of the symptoms associated with the menopause. The duration of the flushing period was also very varied. In the majority it occurred on and off for a period of about two years, in many cases it lasted five to ten years, while a considerable number, even some in their seventies and eighties, said that they had never been entirely free from flushing since the change of life. It was a common experience for the flushing to occur or to be more marked during a state of fatigue or of debility after an illness.

TABLE I.—*Showing frequency of symptoms*

—	Percentage frequency amongst—		
	Total women.	Married women.	Single women.
No symptoms	15·8	13·8	20·4
Flushing	62·3	64·8	59·1
Hæmorrhage	20·9	22·6	17·1
Giddiness	39·7	42·3	34·3
Headache	44·6	45·9	41·7
Nervous instability ..	30·9	30·4	32 0
Pain in breasts	6·3	6·7	5 0
"Rheumatic" pains ..	23·7	24·9	21·0
Change in thyroid.. ..	2·0	1·8	2 5
Miscellaneous	1·3	1·1	1·9
Obesity	34·2	39·4	22·7

(*b*) *Other symptoms.*—Of the other symptoms inquired into it must be explained that under the heading "rheumatic" pains are grouped cases of arthritis and fibrositis, it being found impossible to *differentiate between these conditions in many of the* histories obtained. The term hæmorrhage was used for all cases in which excessive uterine loss was noted, either on one or more occasions or extending over several periods.

As will be seen in Table I., flushing, headache, giddiness, obesity, and nervous instability were in numerical order the most frequent among the married women. The sequence in the case of single women was flushing, headache, giddiness, nervous instability, and obesity. "Rheumatic" pains and hæmorrhage were next in frequency in both groups, and pains in the breast and changes in the thyroid were at the lower end of the scale. Greater frequency, in varying degrees, was shown, in the case of married women, of all the following symptoms: flushing, headache, giddiness, "rheumatic" pains, hæmorrhage, pains in the breast, and obesity. In the last-mentioned, the relative disparity was very marked, the percentage value *for single women being only 57 per cent. of that* found for married women. On the other hand, there was a slight excess (5 per cent.) in the proportion of nervous instability amongst single as compared with married women, and, although the actual number of thyroid changes was very small in the two groups, the proportion among the single was 30 per cent. greater than that among the married.

INCAPACITY DUE TO THE MENOPAUSE

Under the heading "incapacitated" were grouped all the women who, on account of some disturbance of health attributed to the menopause, were obliged to lie up or absent themselves from their work on one only or on more occasions. The proportion was 10·3 per cent. In this there was little difference between the married and single women, the percentage being 10·9 and 9·1 respectively.

In view of the general impression acquired from the literature on the subject, it was somewhat surprising to find that approximately 900 out of 1000 unselected women stated that they had carried on their daily routine without a single interruption due to menopausal symptoms. In support of these assertions, it may be added that one of the difficulties in collecting data for the investigation from other than patients has been the uncertainty of heads of departments in business houses as to which of the women employed should be questioned, since in so many over 50 years of age no signs of having passed the "change of life" had been detected. A similar problem was experienced in approaching women of all classes, who, in daily contact with others, had revealed no menopausal disturbance, such as irritability of temper commonly thought to be inseparable from this phase of a woman's life.

AGE OF ONSET AND CESSATION OF MENSES

In questioning a number of women, most of whom were over 50, it may be surmised that it was not possible to get accurate information of events and sensations which had occurred over 35 years previously. It was, however, found that, even in the very old women, recollection as to the age of onset and the early experiences of menstruation were firmly fixed. It was not at all uncommon for the exact date and day of the week of the first occurrence of menstrual discharge to be remembered. This was not so with regard to details concerning the "change of life." Several were unable to state their exact age at the last period, even if only five years previously, though the large majority could give definite information as to age and symptoms.

It was found that the ages of onset of menstruation ranged from 9 to 21 years. In the age-group 13–15 years, inclusive, 55 per cent. of the total observations were located. In approximately 13 per cent. of the whole series, the menstrual periods did not begin until after the age of 17 years. The age of the last period ranged from 23–60 years, excluding one who stated that she continued to menstruate regularly until she was 66, and another until she was 73. Cases of artificially induced menopause were not included. The proportion of women who had their last period before reaching their 40th year was 8 per cent. In the ensuing five years, 22·5 per cent. reached their menopause, and between 45 and 55 years 64·7 per cent. of the total cases occurred. At the age of 55 and upwards, the proportion fell to less than 5 per cent. The maximum frequency for both single and married women occurred at 50 years. But the marked excess in this age-group, followed by the marked defect in age-group 51, as seen in Table II., is in part due to the tendency for women whose memories were not accurate to state their age in "round figures." A similar tendency is exhibited around the ages 40 and 45.

TABLE II.—*Showing the age-incidence in individual years of those women who had their menopause between the 38th and 52nd year*

Age in years.	Married	Single.	Total women.	Age in years.	Married	Single.	Total women.
38	13	3	16	46	48	19	67
39	12	2	14	47	39	18	57
40	63	29	92	48	61	30	91
41	26	9	35	49	56	23	79
42	38	11	49	50	114	53	167
43	39	16	55	51	26	16	42
44	21	7	28	52	55	23	78
45	71	25	96	(38–52) Total.	682	284	966

The next questions considered were the possibility of any inter-relation between the ages of onset and cessation of the menses, also whether the age of menopause was affected by childbearing. By various methods of calculation and correlation, it was proved that there was no relationship exhibited in the data between the menstrual and menopausal ages of either married or single women. When menstruation began at 13, the mean age of cessation was 47·3; when it began at 18, it was 47·5. Although the mean age at menopause declines for menstrual ages over 19, not much importance can be attached to the decrease, as the values are based on small numbers. It was also found, by statistical analysis, that childbearing exerted no influence whatever on the age at the menopause. It was noted, however, in taking the histories, that a considerable number of women stated that they had not menstruated since their last confinement, although this was definitely earlier in some cases than the usual menopause age.

EFFECT OF CERTAIN FACTORS ON THE PREVALENCE OF SYMPTOMS

(*a*) *Age at the last period.*—In most instances there was little evidence that age was an influential factor in the occurrence of symptoms. There were, however, certain exceptions. The proportion of the cases of hæmorrhage increased with the age. On the other hand, there was a suggestion that obesity declined with the age.

(*b*) *Number of miscarriages.*—Among women who had had no miscarriage there was a tendency for the occurrence of menopausal symptoms to be relatively less than amongst women who had had miscarriages, especially with regard to pains in the breast, "rheumatic" pains, and obesity, but there was little evidence that an increase in the number of miscarriages accentuated the prevalence of symptoms.

(*c*) *Number of pregnancies.*—There was a tendency for the individual symptoms to be relatively more frequent amongst women who had conceived. There is, however, no substantial evidence to show that the proportion of symptoms increased with the number of conceptions, except in the group of women who had ten or more pregnancies. Amongst the 837 married women, 15·5 per cent. were never pregnant, 38·5 per cent. had 1–3 pregnancies, 7·4 per cent. had ten or more. In the last group, in which the proportion of symptoms was significantly higher, were included—

6 women who had 14 pregnancies.
5 ,, ,, ,, 15 ,,
2 ,, ,, ,, 16 ,,
1 ,, ,, ,, 17 ,,

There was, however, one symptom—namely, nervous instability—which was unaffected by pregnancy in the data. The prevalence of this symptom was just as high amongst the nullipara as amongst those who had had many children. In all probability it was a condition which prevailed among a class of women long before the menopausal age was reached

RELATIONSHIP BETWEEN MENSTRUAL AND MENOPAUSAL SYMPTOMS

In previous paragraphs we discussed the relationship between the menstrual and the menopausal ages, and found that for all practical purposes they were unrelated—a knowledge of the one being of little use in predicting the onset of the other. These two physiological phases were then considered from another aspect. Is a woman who suffered from dysmenorrhœa more likely to suffer from symptoms during the menopause than a woman in whom menstruation was normal? To answer this question, the menstrual and menopausal data were sorted into categories. as shown in Table III.

TABLE III

Menstruation.	Married menopause.			Single menopause.			All women menopause.		
	N.	S.	Total	N.	S.	Total	N.	S.	Total
Normal	193	106	299	76	22	98	269	128	397
Severe ..	201	268	469	106	114	220	307	382	689
Total ..	394	374	768	182	136	318	576	510	1086

N. =normal; S. =severe.

It will be observed that the proportion of normal menstruation with severe menopause in married women was 106/299 (35·45 per cent.); in single women, 22/98 (22·45 per cent.); and among all women, 128/397 (32·24 per cent.). The proportion of severe menstruation with severe menopause in married women was 268/469 (57·14 per cent.); in single women, 114/220 (51·82 per cent.); and among all women, 382/689 (55·42 per cent.).

The differences between these values—35·45 per cent. and 57·14 per cent. for married; 22·45 per cent. and 51·82 per cent. for the single; 32·24 per cent. and 53·42 per cent. for all women—are greater than those which are likely to arise by mere chance. Hence we conclude that according to these data there is some evidence that a normal menstruation tends to be followed by a normal menopause and vice versa, and that the association is slightly more defined amongst single women than married women.

It must be borne in mind that the majority of women from whom these figures were obtained, being over 55, had not so much opportunity for healthy development open to them as have girls of the present day. 57·5 per cent. of them were troubled with some menstrual disability, whereas the proportion of cases of dysmenorrhœa amongst young women is now much smaller. If then a normal menstruation is found to be associated with a symptomless menopause, there may be reason to hope that in the future there will be less disturbance of health at the "change of life."

PREVIOUS HEALTH AND MENOPAUSAL SYMPTOMS

Notes as to previous health were made in the schedules for the purpose of examining whether this factor influenced in any way the type of menopausal symptoms. In many cases the histories were indefinite, and the value of statements regarding past illnesses were difficult to assess. It was interesting to note, for instance, the importance attached to "heart trouble" by some who had reached a ripe old age. Several of the old women, including one in her 90th year complained that they had "always suffered from a weak heart," though their health had been otherwise good—no credit being allowed to the maligned organ for the fact that it still continued to beat. The records of previous health were, however, classified under "good," "fair," and "bad," and when the necessary calculations were made from this crude basis, it was found that there was only a small degree of relationship between the previous health and the type of menopausal symptoms, the coefficient of contingency being 0·203 for married and 0·137 for single women.

SUMMARY

From the analysis of the data the following points emerge:—

1. The proportion of women who carried on their usual occupation *without any interruption* due to symptoms attributed to the menopause was 89·7 per cent., the difference between the married and unmarried groups being insignificant.

2. The percentage of women free from all menopausal symptoms was 15·8. The percentage of women relatively free, flushing being the only symptom, was 20·6. The proportion in each case was greater in single than in married women.

3. Greater frequency in the following symptoms were found amongst married women: flushing, headache, giddiness, "rheumatic" pains, hæmorrhage, pains in the breast, and, markedly so, obesity. In nervous instability and change in the thyroid, the larger proportion was amongst the unmarried.

4. There was little or no correlation between the age of onset of menstruation and the age at the last period for either married or single women. Notwithstanding that a considerable number of women stated that the menses had not recurred after the last confinement—which was, in some cases, definitely earlier than the usual menopause age—the analysis showed that childbearing, even when allowance was made for age at marriage, in no way influenced the age at the menopause.

5. There was some evidence that normal menstruation tended to be followed by a normal menopause, and a history of dysmenorrhœa by more marked menopausal symptoms. This was slightly more defined for single than married women.

6. Previous health was a factor of no marked importance in influencing the onset or severity of menopausal symptoms.

The members of the subcommittee who presented the above report to the Council of the Medical Women's Federation were as follows: Lady Barrett, M.S. (chairman), Prof. Winifred Cullis, D.Sc., Dr. Letitia Fairfield, London; Miss Ruth Nicholson, M.S., Liverpool; Dr. Mona Macnaughton, Newcastle-on-Tyne; Dr. Cecilia F. Williamson, Ipswich; and Dr. Alice E. Sanderson Clow (hon. sec.), Cheltenham.

THE DOCTOR'S DAY

"Come, tell me how you live," I cried,
"And what it is you do!"

X.—THE CORONER

THE principal duty of a coroner is to investigate all sudden deaths of unknown cause, deaths from violence of all kinds, and all unnatural deaths—e.g., deaths from poison, anæsthetics, alcoholism, or industrial diseases. Most of the deaths requiring investigation are reported to the police station or to the coroner's office, and the coroner's officer of the borough in which the death took place then makes his inquiry and presents a written report each day to the coroner. The perusal of all these reports is the first daily duty of the coroner, and he then decides whether an inquest will be necessary, or whether the doctor can properly and safely certify the cause of death, or whether a post-mortem examination would be likely to clear up the doubt and so avoid the necessity for an inquest. If he decides that an inquest ought to be held, then he fixes the time, directs what witnesses should be summoned, orders the removal of the body to the mortuary, orders a post-mortem examination, if required, says who is to make it, and issues his warrant for the summoning of a jury when necessary—e.g., a street fatality, or a death from a factory accident. In factory cases notification is sent to the factory inspector of the time of the inquest, and if there is suspicion that the case may be one of murder or manslaughter then the coroner informs the Criminal Investigation Department at New Scotland Yard, and inquiries are set on foot by them.

Roughly about half of the cases reported to the coroner can be dealt with under the Act of 1926 by ordering a post-mortem examination, usually by an expert pathologist; if this reveals a natural death, then the case can be so certified by the coroner and no inquest will be required. Other cases requiring his attention are those where a death has occurred rather suddenly and unexpectedly, and, although there may not be any suspicion that the death is other than a natural one, yet the doctor may feel it his duty to inform the coroner of the death. A little inquiry will often clear up such a case, and will enable the coroner to authorise the doctor to issue a certificate of death. Then there is now an Act which requires all deaths of persons whose bodies it is sought to remove out of England to be reported to the coroner; a consideration of the death certificate and the general circumstances surrounding the death will generally satisfy the coroner that there is no need to hold an inquest.

INQUESTS AND JURIES

Having thus cleared his table the coroner will proceed to dispose of his daily list of inquests. He may have as many as 1500 cases reported to him in a year, and he will probably hold not far short of 800 inquests. Fortunately, a good many of these an be held without a jury. or he would find it mpossible to get through. All deaths from street ccidents. all factory deaths. and, of course. all ases of murder and manslaughter require juries: n such cases there are generally counsel or solicitors. or both. and the proceedings are accordingly considerably lengthened. After the relevant witnesses have been examined and cross-examined. the coroner sums up, explains to the jury the law. generally of negligence. marshals the facts proved in evidence. directs their attention to inconsistencies and improbabilities and contradictions, and their effect upon the weight of evidence. asks the jury to decide upon the facts which they accept as the correct ones. to apply the law to those proved and accepted facts. and to return a verdict upon them accordingly. After the verdict the inquisition is signed. the fees are paid. and the court is closed.

Very rarely there is a verdict of murder or manslaughter, and in these cases the coroner has to read over the depositions to each witness. sign them and get them signed by him: he has to issue his warrant for the arrest of the accused and for his committal to prison to await trial: to give bail in case of manslaughter if he so decides: to bind over the witnesses to give evidence at the Old Bailey: and. finally. to get the formal inquisition signed by the jury. Such committals are now very few. for. under the Act of 1926. where a person has been charged before a magistrate with these offences the coroner adjourns his inquest until the termination of the criminal proceedings. From time to time, however, the coroner has cases in which. although there is suspicion. it is not sufficient to justify the police in making an arrest. and he has to deal with the matter at length. Criminal abortions belong to this class and are most unsatisfactory and difficult. for there is generally a conspiracy of silence and deceit. I believe there is a large number of these cases in London at present, but few of them come before us. When they do come they are so veiled in secrecy and so cleverly camouflaged that it is seldom possible to bring the crime home to the perpetrator. The incriminating evidence consists. as a rule. of statements made by the deceased person or by an accomplice which cannot well be admitted in such a serious charge.

DIFFICULT CASES

Complicated street smashes. where two or more vehicles are involved. present great difficulty to the coroner. Obscure cases of food poisoning. unexplained fatal fires. mysterious explosions. house collapses. flood fatalities. all kinds of factory accidents. river collisions. suicides. and scores of other problems present themselves for solution in the course of the year. All. or very nearly all. can be solved by close attention, by expert assistance. and by adjournments and continuous investigation. In cases of great public importance in London the L.C.C. will always give the coroner every assistance he may require in the matter of engaging and paying technical experts to investigate really difficult problems; thus the coroner's court may find itself listening to great engineers. architects. chemists. metallurgists. fire experts, flying experts. explosives experts, building research workers, ventilation engineers. or railway signal technicians. The viewing of the locus in quo enables him to understand what would otherwise be almost unintelligible. In certain cases of sudden death the autopsy may fail to reveal a definite cause of death; while some coronary disease or heart disease may be present. it is well within the bounds of possibility that these are not the real cause of death. Careful inquiry into the clinical history, and the absence of all signs or symptoms of poison may enable the coroner to pass the case. but it is as well. when in doubt. to exclude poisoning by ordering an analysis. In London this is easy, for we are empowered to engage and pay analysts when we feel it desirable to have a chemical or bacteriological analysis performed. It will be remembered that in the Seddon case. the Armstrong case, the Greenwood case. the Duff case. and the earlier Pritchard case medical certificates of natural deaths were given by medical practitioners. but subsequent analyses showed arsenic to be the cause of death in all these cases—a rather disturbing reflection. I look upon all sudden and unexpected deaths as suspicious if there is a history of vomiting and diarrhœa. and I take steps to avoid being led astray by such vague certificates of the cause of death as gastritis. Then. again. one must be watchful for deaths which appear to be due to cerebral hæmorrhage but which may be due to narcotic drugs.

Suicides and street fatalities provide us with the bulk of our cases for inquest. and when the suicide uses the now fashionable gas oven they are simple enough. Farewell letters in the writing of the deceased are a blessing to the busy coroner in suicides. but where the death took place as the result of a fall from a window. and no writing is left by the deceased. and there is an astute solicitor or counsel. the case may not be quite so easy. A diligent search by an experienced coroner's officer will often disclose some document which throws a light upon the cause of death: it is surprising how often such papers are overlooked. Finger-marks in the room and particularly on the window-sill now and then enable us to arrive at a conclusion.

NO LIFE SO INTERESTING OR VARIED

After a pretty long experience of life. and a considerable acquaintance with people engaged in all kinds of professions and businesses. I know of no life which is so interesting and so varied as that of a London coroner. The chief charm of the life lies in its complete independence. So long as you conduct your duties with efficiency no one can interfere with you. The Lord Chancellor can remove you from office. but only for incompetence or actual misconduct. and I have never heard of this power having been exercised. You arrange the work to suit public convenience and. subject to that. to suit yourself. One day it may be very heavy. but the next may be free. The work is always lightest when the weather is at its best. heaviest when the gloom and cold of winter render work preferable to leisure. If after months of continuous work you feel stale and weary of tragedies you can take a holiday without asking anyone's permission. All you have to do is to hand over the duties to your deputy, pay him his fee. and go away. Coroners who were appointed after the passing of the Act of 1926 must retire at 65 years of age. but in London they then receive a (maximum) pension of nearly £1000 a year, which, being non-contributory. is adequate. As regards prospects. we in London are most of us rapidly approaching the retiring age. so there will be plenty of vacancies in a few years. and I know that some of my colleagues are without assistant deputies because they cannot find suitable men.

The newly qualified medical man who is desirous of becoming a coroner may wonder how to solve the problem of earning his living as a doctor and getting called to the bar at the same time. But the bar examinations. though difficult and at times dull. are far easier than those of the medical student. Tuition courses can be carried on by correspondence, the eating of *dinners in Hall* is just a pleasant formality. and a call to the bar should be within the reach of the average doctor within a couple of years. If in practice in London he can pick up the routine work of a coroner by attending his inquests for a few weeks or months: once that knowledge is acquired an assistant deputyship. followed by a deputyship. should be obtainable in due course. The deputy takes the place of the coroner during his absence. through illness or other cause. such as holidays. and it is quite easy to carry on a practice at the bar. or in medicine, whilst holding one of these appointments and waiting for full coronership.

menstruation with severe menopause in married women was 268/469 (57·14 per cent.); in single women, 114/220 (51·82 per cent.); and among all women, 382/689 (55·42 per cent.).

The differences between these values—35·45 per cent. and 57·14 per cent. for married; 22·45 per cent. and 51·82 per cent. for the single; 32·24 per cent. and 53·42 per cent. for all women—are greater than those which are likely to arise by mere chance. Hence we conclude that according to these data there is some evidence that a normal menstruation tends to be followed by a normal menopause and vice versa, and that the association is slightly more defined amongst single women than married women.

It must be borne in mind that the majority of women from whom these figures were obtained, being over 55, had *not so much opportunity for healthy development* open to them as have girls of the present day. 57·5 per cent. of them were troubled with some menstrual disability, whereas the proportion of cases of dysmenorrhœa amongst young women is now much smaller. If then a normal menstruation is found to be associated with a symptomless menopause, there may be reason to hope that in the future there will be less disturbance of health at the "change of life."

PREVIOUS HEALTH AND MENOPAUSAL SYMPTOMS

Notes as to previous health were made in the schedules for the purpose of examining whether this *factor influenced in any way the type of menopausal* symptoms. In many cases the histories were indefinite, and the value of statements regarding past illnesses were difficult to assess. It was interesting to note, for instance, the importance attached to "heart trouble" by some who had reached a ripe old age. Several of the old women, including one in her 90th year complained that they had "always suffered from a weak heart," though their health had been otherwise good—no credit being allowed to the maligned organ for the fact that it still continued to beat. The records of previous health were, however, classified under "good," "fair," and "bad," and when *the necessary calculations* were made from this *crude* basis, it was found that there was only a small degree of relationship between the previous health and the type of menopausal symptoms, the coefficient of contingency being 0·203 for married and 0·137 for single women.

SUMMARY

From the analysis of the data the following points emerge:—

1. The proportion of women who carried on their usual occupation without any interruption due to symptoms attributed to the menopause was 89·7 per cent., the difference between the married and unmarried groups being insignificant.

2. The percentage of women free from all menopausal symptoms was 15·8. The percentage of women relatively free, flushing being the only symptom, was 20·6. The proportion in each case was greater in single than in married women.

3. Greater frequency in the following symptoms were found amongst married women: flushing, headache, giddiness, "rheumatic" pains, hæmorrhage, pains in the breast, and, markedly so, obesity. In nervous instability and change in the thyroid, the larger proportion was amongst the unmarried.

4. There was little or no correlation between the age of onset of menstruation and the age at the last period for either married or single women. Notwithstanding that a considerable number of women stated *that the menses had not recurred after the last* confinement—which was, in some cases, definitely earlier than the usual menopause age—the analysis showed that childbearing, even when allowance was made for age at marriage, in no way influenced the age at the menopause.

5. There was some evidence that normal menstruation tended to be followed by a normal menopause, and a history of dysmenorrhœa by more marked menopausal symptoms. This was slightly more defined for single than married women.

6. Previous health was a factor of no marked importance in influencing the onset or severity of menopausal symptoms.

The members of the subcommittee who presented the above report to the Council of the Medical Women's Federation were as follows: Lady Barrett, M.S. (chairman), Prof. Winifred Cullis, D.Sc., Dr. Letitia Fairfield, London; Miss Ruth Nicholson, M.S., Liverpool; Dr. Mona Macnaughton, Newcastle-on-Tyne; Dr. Cecilia F. Williamson, Ipswich; and Dr. Alice E. Sanderson Clow (hon. sec.), Cheltenham.

THE DOCTOR'S DAY

> "Come, tell me how you live," I cried,
> "And what it is you do!"

X.—THE CORONER

THE principal duty of a coroner is to investigate all sudden deaths of unknown cause, deaths from violence of all kinds, and all unnatural deaths—e.g., deaths from poison, anæsthetics, alcoholism, or industrial diseases. Most of the deaths requiring investigation are reported to the police station or to the coroner's office, and the coroner's officer of the borough in which the death took place then makes his inquiry and presents a written report each day to the coroner. The perusal of all these reports is the first daily duty of the coroner, and he then decides whether an inquest will be necessary, or whether the doctor can properly and safely certify the cause of death, or whether a post-mortem examination would be likely to clear up the doubt and so avoid the necessity for an inquest. If he decides that an inquest ought to be held, then he fixes the time, directs what witnesses should be summoned, orders the removal of the body to the mortuary, orders a post-mortem examination, if required, says who is to make it, and issues his warrant for the summoning of a jury when necessary—e.g., a street fatality, or a death from a factory accident. In factory cases notification is sent to the factory inspector of the time of the inquest, and if there is suspicion that the case may be one of murder or manslaughter then the coroner informs the Criminal Investigation Department at New Scotland Yard, and inquiries are set on foot by them.

Roughly about half of the cases reported to the coroner can be dealt with under the Act of 1926 by ordering a post-mortem examination, usually by an expert pathologist; if this reveals a natural death, then the case can be so certified by the coroner and no inquest will be required. Other cases requiring his attention are those where a death has occurred rather suddenly and unexpectedly, and, although there may not be any suspicion that the death is other than a natural one, yet the doctor may feel it his duty to inform the coroner of the death. A little inquiry will often clear up such a case, and will enable the coroner to authorise the doctor to issue a certificate of death. Then there is now an Act which requires all deaths of persons whose bodies it is sought to remove out of England to be reported to the coroner; a consideration of the death certificate and the general circumstances surrounding the death will generally satisfy the coroner that there is no need to hold an inquest.

INQUESTS AND JURIES

Having thus *cleared* his table the *coroner* will proceed to dispose of his daily list of inquests. He may have as many as 1500 cases reported to him in a year, and he will probably hold not far short of 800 inquests. Fortunately, a good many of these so to what amount. Here, as is pointed out in this correspondence, the doctor is definitively tried by his colleagues who know and realise his difficulties. The report of the panel committee goes to the Ministry of Health and to the insurance committee. The Ministry may think the report does not suggest adequate compensation to the public funds for the extravagance indicated, and the matter is then referred to two doctors and a lawyer, who start de novo. In this inquiry the practitioner may be helped by a legal man.

This procedure, which should by now be familiar to the parties concerned, does not, in reality, lead to many cases of surcharging. We agree with the Glasgow critics that it is a pity there have been no cases of investigation of under-prescribing. The areal average must be arrived at by taking into consideration those above the average and those below, and it would seem only fair to require an explanation from practitioners whose average is much below that of the area. Patients are entitled to proper and sufficient medicines, and if a practitioner does not give sufficient medicines he is breaking regulations as much as the over-prescriber. And these patients are not very likely to make complaint. The public are rather fond of cranks, and are apt to think that the doctor who says, "I don't believe in medicines" is cleverer than his brother practitioner. It does not occur to them that he may not know how to use drugs properly.

Appeal to a court of law against surcharge commends itself to newspaper correspondents in Glasgow. But this is a double-edged weapon; for if a disgruntled doctor is to be allowed to appeal against the decision of Ministry, panel, or insurance committees in a highly technical matter on which he has been tried by his own colleagues, these committees too must be allowed to appeal to the courts in cases in which the Minister decides against them. The important matter is that justice should be done. From a somewhat prolonged survey we have yet to discover an official of the Ministry, or a court of referees set up by it, failing to interpret the regulations in an impartial manner.

Mileage in the North Riding

At a meeting of the insurance committee for the North Riding of Yorkshire it was reported that the inability to find a successor to the medical practice at Appleton Wiske had resulted in the allocation of patients to doctors in the surrounding area which would mean an additional call of £210 on the mileage fund. This, it was suggested, might involve hardship on insured persons over a wide area; some patients would require to make journeys on a restricted bus service to Northallerton to consult their medical man, and to wait several hours before they could make the return journey. A substantial subsidy to a doctor to live at Appleton Wiske would be more economical than a charge on mileage fund, but there seems to be no suitable house in the place, and the practice is so poor that even with a subsidy of £200 a medical man could not live on the spot.

Attendance on Poor Old People

Last month an elderly woman died in East Ham from perforated gastric ulcer without having been seen by the doctor. At the inquest the district medical officer stated in evidence that this was an old public assistance patient with many troubles, and after seeing her on Nov. 16th he told the relatives to inform him if she became worse, the next thing he heard about one month later was she was dead. "I have to attend all the old cases of East Ham," he is reported as saying, "and I cannot see all these people as often as I should like," adding: "I have been here five years, and this is the first time it has happened—owing mainly to good luck." Why, it may be asked, cannot these old people have a choice of panel doctors, responsible to some committee comparable to those of the National Health Insurance system? Were the public assistance committee to join up with the public medical services, as they exist in many parts of the country, this over-pressure of work on doctors would be avoided and these old people would receive the standard of medical practice to which they are entitled.

Economy Gone Wrong

The London pharmaceutical service subcommittee recently found a chemist guilty of a breach of the terms of his service for failing to supply medicaments ordered. The complainant alleged delay. The facts were that a doctor ordered sod. morrh. 10 per cent., one 2 c.cm. ampoule for intravenous injection, the insured person being told that he could have this if he would call the following evening. Inquiries by the chemist elicited that the manufacturers could not supply a single ampoule, and that the smallest box contained five ampoules. An approach was then made to the practitioner, who was requested to order five ampoules, but refused. Three days later the medicament had not been supplied, notwithstanding that the insured person had called several times. The practitioner then gave him an injection, using his own stock for the purpose. The chemist admitted that he did not dispense the prescription, and relied on the defence that the smallest quantity of ampoules he could obtain from his wholesale house was five, whereas the prescription ordered only one and the prescriber refused to amend the order. He did not want to have left on his hands four ampoules for which he might not be able to find a customer. This point is, however, covered by Section 14 of the Drug Traffic, which forms part of the terms of service:—

> Where a proprietary preparation is required by the prescription to be supplied without dilution or admixture, and is available only in packages of definite sizes, a chemist may, if the preparation does not come within the scope of the Dangerous Drugs Regulations, supply the size approximating most closely to the quantity of preparation prescribed where this quantity does not correspond exactly to the quantity contained in a package. Payment for quantities of proprietary preparations other than those prescribed will be made only where the chemist forwards to the pricing office, with the appropriate prescription form, particulars of the quantities supplied.

The chemist should have supplied five ampoules and marked the prescription accordingly. But it seems rather hard on a chemist who went to quite a lot of trouble to supply what was asked for, and hesitated only from a desire for economy, should be found guilty of a breach of the terms of service.

SUN, AIR, AND SEA-BATHING IN HEALTH AND DISEASE.—Sir Henry Gauvain, medical superintendent of Lord Mayor Treloar Cripples' Hospital and College, Alton, Hants, will lecture on Sun, Air, and Sea-bathing in Health and Disease, in the Great Hall of the British Medical Association, Tavistock-square, W.C., on Tuesday, Feb. 21st, at 8 P.M. The lecture is the fifth Sir Charles Hastings Lecture, inaugurated by the British Medical Association and designed to afford public information from high authorities on matters of general health interest. The chair will be taken by the president of the Association, Lord Dawson of Penn, and after the lecture relevant questions in writing are invited. Admission will be free by tickets obtainable on application to the financial secretary, B.M.A. House, Tavistock-square, London, W.C.1.

PANEL AND CONTRACT PRACTICE

A Scheme of Dental Contract Practice

WE have received from the British Dental Association a scheme of contract practice for dental work which is designed to assist the British Medical Association's proposal for a general medical service for the nation. In this proposal the view was expressed "that arrangement should be made by the community with the dental profession for a comprehensive dental service." The scheme presented by a special committee of the Dental Association deals primarily with insured persons, but it could be adapted to include dependents. It is designed to prevent dental disease and to give treatment in the very earliest stages. Dental health is shown by experience to be best maintained by examination and treatment at regular intervals. The committee thinks that a per-capita payment would be best in the public interest, as it leaves the dentist free to exercise his professional judgment, and ensures the maintenance of contact between patient and dentist so necessary to secure dental fitness. It suggests that the family dentist would become parallel to the family doctor, and that whilst some control may be necessary limits should be placed on third-party interference. In brief the scheme is this:—

Each participating dentist should provide general dental treatment to maintain every insured person on his list in a dentally sound condition in return for a fixed capitation rate per annum. Before an insured person is accepted he must be dentally sound. If he is not dentally sound the dentist would have to make him sound and be paid according to a definite scale of fees for the necessary work done. The control of the scheme would be on lines parallel to that of medical benefit under the Act, with Ministry of Health, insurance committee, and dental panel committee; a dental service subcommittee would deal with complaints, as does the medical service subcommittee.

All insured persons, after a short qualifying period, would be eligible for treatment, to include scaling, gum treatment, filling with plastics, root treatment, extractions, with local and general anæsthetics (other than prolonged), provision of dentures for maintenance of reasonable standard of mastication and general appearance, repairs, and remakes. Such things as gold and porcelain fillings, radiograms, crowns, and bridges, orthodontic apparatus, would not be included, and might be provided at an extra charge, with permission of the insurance committee. Payment to be subject to revision, but an adequate service could be provided, the committee thinks, at a capitation rate between 12*s.* 6*d.* and 16*s.*

Dentists would be required to provide suitable waiting-room and surgery accommodation, to keep records, to have stated hours of availability, and to give necessary emergency treatment. The patient would be required to be examined periodically, to be punctual, and to carry out instructions.

This scheme is theoretically good, but unfortunately the parallel between it and the medical scheme is not close in that, whilst there are quite a number of insured persons who are really fit and do not require medical attention, this is hardly ever so with their dental condition. There would thus be a very high initial cost in putting every insured person's mouth into a dentally fit condition before acceptance under the scheme. Again, practically all dental work is operative, and most insured persons would require several periods of 15–20 minutes for fillings before their mouths could be pronounced dentally fit. Most doctors can do all that is necessary for an insured person in five to ten minutes at the bedside; per contra they waste time in travelling from door to door waiting on doorsteps which the dentist does not have to do. Clearly there would have to be definite limitations of lists to enable the work to be properly carried out, and it is doubtful if the dental profession is sufficiently numerous for the purpose. Nothing is said in the scheme as to how the money is to be raised for the work, but obviously one method would be to increase the health insurance stamp on cards. It would be interesting to hear what the actuaries would say was necessary to finance such a scheme, but with an insured population of 15 millions the cost at 15*s.* per head would be over 11 million pounds, apart from administration or materials. A 100-gallon cylinder of gas at 5*s.* 8*d.* may suffice for ten average cases—still an expensive item; an anæsthetic fee at 10*s.* 6*d.* a case, payable to the doctor, would cost quite a lot.

It is thought that some such dental scheme will come into existence, for the present system of payment to dentists for work done is not satisfactory because of the frequent inability of the insured person to pay his share of the cost, when the approved society agrees to pay the other, and because dental benefit is not a statutory benefit but an additional benefit, entirely in the hands of approved societies to give or not to give as they think fit. Many societies at the present time do not give dental benefit at all, and many more refuse dental benefit to women. Some insured persons are therefore not getting dental benefit at all; others could get it if they could afford to pay their share of the cost. This is hardly a satisfactory state of affairs in view of the importance now attached to maintenance of dental fitness.

Surcharging

The surcharge of insurance practitioners in Glasgow is giving rise in newspapers to headlines such as "Danger of efficient prescriber being penalised," "Where duty becomes offensive," and so forth. However much we may regret the necessity of regulations for this purpose, or, for that matter, for any purpose under the National Health Insurance Acts, with such huge numbers of patients and with so many doctors, it is not surprising to find some who do not play the game; and as the supply of proper and sufficient medicines is paid for out of public funds it does become necessary to protect those funds from over-generous use—e.g., the prescription of a pound of cotton-wool with a proportional amount of lint for the treatment of a cut finger; or, as in a reported case, of 5 hundredweight of malt and cod-liver oil in one quarter for the patients of a firm of doctors. The procedure adopted is now fairly well known. A doctor's prescribing cost is found by pricing all his prescriptions and dividing by the number in each quarter; if this average is markedly above the average of all the other doctors for the same area the prescriptions are scrutinised and it is thus discovered whether there is anything special in this batch to account for the higher cost. For example there may be much insulin ordered or polyvalent antistreptococcal serum or some obviously necessary high costing medicament which would raise the average cost.

The next procedure is for the regional medical officer to interview the practitioner, generally with a member of the panel committee for the area, to hear his explanation of the higher cost. If this is satisfactory nothing more is heard of the matter, but if not satisfactory—some cases in this category seem to indicate a complete lack of interest or responsibility in the use of public money—the matter is referred to the panel committee, who again interview the practitioner, hear his explanation, and thereupon decide whether there has been extravagance, and if himself whole-heartedly into the task of reorganising the pathology department from the point of view of teaching. Firmly convinced that a knowledge of the principles of pathology was essential for a proper appreciation and understanding of clinical medicine and surgery, he did all in his power to ensure that his students had ample opportunities for acquiring that knowledge. He was conscientious and thorough in all his teaching, and his lectures were models of systematic method. He established and organised a small teaching museum, in which the specimens are arranged in a manner which enables the student to study not only the diseases of individual organs but also the effects of the commoner diseases on the various organs in the body. The catalogue, which contains a detailed description of each specimen, was his own work, and students at Guy's have taken full advantage of these facilities, of whose teaching value there can be no doubt. He was an occasional contributor to the Guy's Hospital Reports, in which he published an important paper on Hæmochromatosis in 1929, and he was also responsible for a series of experimental investigations in connexion with the work on puerperal sepsis by the late Dr. Remington Hobbs.

Donaldson was a many-sided man, having, in addition to his medical qualifications, diplomas both in tropical medicine and public health, while he was a sound classic and a good French and German scholar. His handbook on practical histology, a second edition of which appeared last year, contained much valuable teaching. In the first edition the work only attempted to be a guide to morbid histology, but in the later issue the scope of the work was extended, and concise accounts of the pathology and morbid anatomy of different lesions were included with descriptions of their histology. The addition of short sections on parasitology and histological technique made of the work a text-book in which the whole subject is treated comprehensively; the essential points were reproduced in a clear manner, accompanied by excellent pictures.

Donaldson's classical training and interests in modern literature made him an attractive conversationalist and a competent critic sometimes inconveniently outspoken. He was a real Scot; he loved the Highlands and Islands, and during the last year had been studying Gaelic in order to get in touch with the people. He was a man of deep religious convictions, whose family life was ideal. He married Annie, daughter of the late John Owen of Blaenau-Festiniog, and is survived by her and their two daughters.

SIR CHARLES CLUBBE, K.B.E., M.R.C.S. Eng.

CONSULTING SURGEON, ROYAL ALEXANDRA HOSPITAL FOR CHILDREN, SYDNEY

With the death of Sir Charles Clubbe, at the age of 78 years, Australia loses one who has been an outstanding personality in the Commonwealth for many years.

Charles Percy Barlee Clubbe was born at Hughenden Vicarage, Buckinghamshire, in 1854, the son of the Rev. Charles Clubbe. He was educated at Uppingham, whence he proceeded to study medicine at St. Bartholomew's Hospital, and obtained the diplomas of M.R.C.S. Eng. in 1876 and L.R.C.P. Lond. in 1877. After holding a house surgeoncy in Kidderminster, he went out to practice in Natal, and was civil surgeon attached to the Army Medical Service during the Zulu War in 1879. At the close of that war he returned to England and was appointed chief resident medical officer to the Manchester Children's Hospital, thus beginning an association with the diseases of children which lasted until his death. In 1883, for reasons of health, Clubbe went out to Australia, and settling in Sydney he was appointed promptly to the Children's Hospital, now known as the Royal Alexandra Hospital for Children. Largely as the result of his personal efforts and work the hospital is held in high esteem by all, and his own success in the early diagnosis and prompt treatment of intussusception was remarkable. He was a member of the staff for over thirty years, and on his retirement retained his position as president of the hospital and chairman of the medical board, while in recognition of his services he was presented with his portrait which is now in the possession of the hospital.

Sir Charles was responsible for founding a department for the diagnosis of diphtheria in Sydney, and later was active in raising funds for the provision of serum for the treatment of infantile paralysis. He was one of the founders of the Royal Australasian College of Surgeons, hon. consulting surgeon to the Deaf, Dumb, and Blind Institute, and at different times was a member of the staffs of the Royal Prince Alfred Hospital, the Coast Hospital, and the Greycliffe Home for Babies. He was for many years chairman of the executive of the District Nursing Association. He was knighted in 1927. His abiding interest in life was the study of the diseases and treatment of children; and the Royal Alexandra Hospital for Children, as it is at present, is a monument to him.

CECIL FOWLER BEADLES, F.R.C.S. Eng.

PATHOLOGICAL CURATOR OF THE COLLEGE

MR. BEADLES

Cecil Beadles, who died on Jan. 3rd at his home at Egham Hill, aged 66 years, came of a family of general practitioners, some of whom practised in Forest Hill and others at New Southgate, when both were villages which had not yet become engulfed by the suburbs of London. He was educated at University College, where he won the gold medal in histology in 1885 and became known to S. G. Shattock, then curator of the College museum. He qualified M.R.C.S. and L.R.C.P. in 1890, and must soon have recognised his unfitness to deal with private patients, for his shyness made him brusque in manner and address. He was house surgeon at the Cancer Hospital for a short time, and from 1892 until 1906 was assistant medical officer at the London County Asylum, Colney Hatch, at a time when it became widely known owing to a disastrous fire causing the death of several inmates. His work here on the degenerative lesions of the arterial system in the insane led to the award of a prize by the Medico-Psychological Association.

In 1906 Beadles resigned his post at Colney Hatch to become an unofficial worker at the Royal College of Surgeons, and two years later he was

OBITUARY

ALEXANDER MITCHELL STALKER, M.D., LL.D. St. And.

EMERITUS PROFESSOR OF MEDICINE IN ST. ANDREWS UNIVERSITY

WE have already recorded the death of Prof. Stalker which occurred on Dec. 24th at the age of 79.

Alexander Mitchell Stalker was the son of Donald Stalker, of Leven, Fife, and was born at Leven in 1853. His early education was received at Leven, but most of his school days were spent at the Royal High School, in Edinburgh, before entering the University as a student. Here he had among his contemporaries the two Seths—Andrew, who became professor of logic and metaphysics, and Young, who became professor of moral philosophy in the University—and Lord Haldane, but Stalker held his own with them. He graduated M.A. with first-class honours in mental philosophy, and throughout his life he retained his interest in philosophy and literature generally. As a medical student he obtained the M.B., C.M. in 1881, and became house physician to Prof. Grainger Stewart at the Royal Infirmary. A period of post-graduate study at Leipzig followed and then a short spell as resident medical officer at Murray House, Perth. Having proceeded to the M.D. degree he then began practice in Dundee, and promptly secured various junior appointments, and in 1888 became physician to the Dundee Royal Infirmary. He now prepared the original draft for a clinical school of medicine in Dundee in association with the adjacent university of St. Andrews, and in 1898 was appointed the first occupant of the chair of medicine, a post which he held for 25 years, during which time he saw the young school steadily develop in strength. During his long period as professor he was entirely responsible for the lectures on the institutes of medicine, and shared with the late Dr. Mackie Whyte the clinical instruction of the students, the two men forming an interesting contrast, for Whyte was precise and methodical, while Stalker, more philosophical in his teaching, appeared interested rather in the individuality of the sick patient than in the scientific study of disease. He was, indeed, of that older scholarly type of physician, preserving a catholic interest in humanity.

PROF. STALKER

[Photograph by Partoon.

In addition to his duties as a professor and as an important member of the hospital staff, Stalker found time to hold other appointments, and was for long medical officer to H.M. Prison, Dundee, where he used his opportunity to study with interest the criminal mentality of the inmates. He retired from the staff of the Dundee Royal Infirmary in 1923, becoming at the same time Emeritus professor of medicine at St. Andrews, and since that time enjoyed fair health till recently; but just before completing his eightieth year he succumbed rapidly to an acute attack of bronchitis. His wife had predeceased him by several years and his eldest son was killed in the war; he is survived by a family of three daughters and three sons, one of whom is at the present time assistant physician to Dundee Royal Infirmary.

A colleague of Prof. Stalker writes: "Prof. Stalker has left behind him the memory of a lovable man, unworldly and generous to a point almost beyond his means. He had a gift for friendship. Of a retiring nature, he was at his best in a small company, where his slow judicious speech with his witty sallies made him ever welcome."

ROBERT DONALDSON, M.D., F.R.C.S. Edin.

PROFESSOR OF PATHOLOGY IN THE UNIVERSITY OF LONDON

WE regret to announce the death of Prof. Donaldson, pathologist to Guy's Hospital, which occurred on Jan. 3rd in the fifty-sixth year of his age, from pneumonia, after a very brief illness.

Robert Donaldson, the son of Mr. James Donaldson, of Corstorphine, was born in 1878 and educated at the Royal High School, Edinburgh, and the University of Edinburgh, graduating in Arts in 1898 and as M.B., Ch.B., in 1904. Having decided to follow a bent towards pathology, he did post-graduate work at Marburg and became demonstrator of pathology first at the University of Sheffield, and later at Bristol, where he was assistant pathologist to the Royal Infirmary. He then held a similar post at the Royal Berkshire Hospital, Reading, was curator of the pathological museum, was in charge of the war hospitals laboratory in Reading, and was appointed consultant bacteriologist to the Berkshire County Council. His pathological work at Reading during the war gained him well-earned credit. Much of it was published in our columns, where he wrote on the ætiological factors in cerebro-spinal fever, as indicated by a severe outbreak in Reading in 1915, and on a series of cases of paratyphoid, the infection probably of military origin. He made careful observations, jointly with Dr. J. L. Joyce, then special surgeon to the Reading War Hospital, on wound treatment, which were embodied in a report to the Medical Research Council, and he published also many bacteriological notes founded on his work at the Reading War Hospital. In 1918 he came to London as lecturer in pathology and forensic medicine at St George's Hospital, where he was curator of the museum. Here he did excellent work for the school for ten years. He was an energetic and careful organiser, equally at home as teacher and as collaborator with the staff in questions of morbid anatomy and bacteriology, covering the large field indicated in his serial contributions and later in his book on morbid histology. He suffered considerably during this period of his life from recurrent attacks of influenza, on the bacteriology of which he wrote at some length in F. G. Crookshank's manual. In 1928 he was appointed Sir William Dunn professor of pathology in the University of London, holding the chair at Guy's Hospital, where he was director of the pathological laboratory. On his appointment he threw glands above detailed were still enlarged and tender. Complete left facial paralysis was present. No signs of any other affection. Wassermann reaction (blood) negative.

Since some virus infections are beneficially affected by protein shock therapy, it was decided to try similar treatment in this case. The results appear to warrant a further trial of the method. On July 2nd T.A.B. vaccine, 50 millions, was given intravenously, with a reaction temperature of 101·5° F. and pulse 96 per minute. The reaction was over in 36 hours. Three days later, on the 5th, a 150 million dose was given. In six hours the temperature reached 102·6° F. and the pulse 80 per minute; 18 hours later the temperature was normal and it was noted that the facial paralysis was less marked. A third injection of vaccine, 200 millions, was given on July 11th; the temperature rose to 101·8° F., the pulse 80 per minute in six hours, but had regained normal in 24 hours. Within four days from this date the eruption had completely disappeared, normal sensation had returned, and the facial paralysis completely cleared up.—I am, Sir, yours faithfully,

London, W., Jan. 10th, 1933. HUGH S. STANNUS.

UNSOUGHT PUBLICITY

To the Editor of THE LANCET

SIR,—I hope it is not too late to offer Sir Harold Gillies ongratulations on the action he has taken with regard o certain publicity recently given him in the press. No doubt those of your readers who have suffered rom misrepresentation or unsought-for publicity will heartily approve of the views expressed in the closing paragraphs of his admirable letter. I can sympathise with his resentment, for, like him, I have been a victim of gross misrepresentation in the lay press. My case was not exactly parallel with his, but my reasons for annoyance were equally real, and a sense of it has lasted.

One night in November, 1931, I was awakened by the elephone about 2 A.M. The person at the other end said he was speaking on behalf of ——, mentioning the name of a well-known London newspaper. He wanted to know f the report appearing in that morning's issue of their own paper was correct—a report to the effect that I had been called in consultation and was going to perform an abdominal operation at 8 A.M. upon a distinguished person, at the time n the public eye. I thought my interrogator was some kind friend attempting a practical joke, so I rang off. I was quickly disillusioned. The telephone rang again. This time it was a representative of the Central News, who assured me that there was a report in a paper which he mentioned, and he wished to know if it were true. Thereafter the telephone seemed to ring incessantly and reporters for various papers sought information so persistently that I was forced to have my telephone disconnected. In the morning I found in the centre of the front page of the paper a report—more than half a column of it—with large black headlines, to the effect that "a hurried consultation had been held. . . . So-and-So had been rushed to —— Hospital, and an operation was to be performed at 8 A.M that morning." Then followed a gratuitous eulogy of myself. Now I did not know the celebrity nor his relatives, nor anybody even remotely connected with him. Neither did I know any of the doctors in attendance, nor had I had communication or consultation with them. There was not a vestige of truth in the whole statement, and no member of the staff of the paper had even telephoned *before publication* to know if the statement had any substance in fact. I consulted the secretary of the Medical Defence Union and Mr. Hempson, the solicitor to the Union, but was informed by both that I had no redress: that there was no libel. With the coöperation of Mr. Hempson I wrote to the editor asking that he should trace this statement to its source, and give me an explanation of how it came to be published without the least attempt at verification. All that I received in reply was: "I am in receipt of your letter of yesterday's date, and am giving the matter my immediate attention." Since then I have heard nothing, nor been vouchsafed an apology.

There should be a limit to the activities of reporters in respect of medical men, and they should verify their statements or reports with regard to medical men before publication. I have no doubt nothing is further from their minds than to harm the person to whom they give unsought publicity. This, however, is precisely the effect that may be produced. Publicity is from time to time inevitable for leaders of the profession, but when younger and not so well-established men are thrown into its glare, and for no legitimate reason, the occurrence does them harm with colleagues, and may alienate friendships and support, and definitely affect their future.

Surely, Sir, something can be done along the lines suggested by Sir Harold Gillies. If a meeting could be arranged between responsible leaders of the press and the medical profession, and the whole matter of press publications affecting medical men could be thoroughly discussed in a spirit of coöperation, would it not be possible to lay down, quoting Sir Harold Gillies, "ethical rules . . . departure from which would be condemned in no uncertain way."

I am, Sir, yours faithfully,
MICHAEL SMYTH.
Wimpole-street, W., Jan. 3rd, 1933.

CONGENITAL MALARIA

To the Editor of THE LANCET

SIR,—The statement in your issue of Dec. 31st last (p. 1463) that "leading authorities on malaria are of opinion that malaria is never congenital" is hardly correct; some leading authorities may be of this opinion, but it is not at all universal. If, in malarial districts, the temperatures of all babies are taken just after birth and blood slides obtained from those with a raised temperature, one will at times find parasites, as I proved myself in Mombasa in 1924 and 1925. In Castellani and Chalmers' "Manual of Tropical Medicine" (1919), on page 1134 you will find this statement:

> "It is now known that the merozoites can, although very rarely, penetrate the placenta and infect the fœtus, giving rise to congenital malaria."

Many workers in the tropics admit the entity of congenital malaria, and I, for one, do not look on Dr. Weyl's case as a very exceptional one. I feel sure that if blood slides were taken of all children at birth in any big hospital in a malarious district many cases would be discovered.

I am, Sir, yours faithfully,
N. P. JEWELL,
Lately in charge European Hospital, Nairobi.
Pinner, Jan. 6th, 1933.

SODIUM-SULPHOMETHYL-STIBANILATE

To the Editor of THE LANCET

SIR,—In a brief report, published in THE LANCET of June 4th, 1932 (p. 1235), of a paper read by me before the medical section of the Asiatic Society of Bengal, it was stated that the compound sodium-sulphomethyl-stibanilate was obtainable in the market under the names of Thio-sarmine, Sulfarsenol, and Kharsulfan. This is incorrect. This compound is an antimonial containing sodium-methylene-sulphonic acid radicle, just as thio-sarmine or sulfarsenol is an arsenical containing the same radicle.

I am, Sir, yours faithfully,
UPENDRANATH BRAHMACHARI,
Medical Secretary, Asiatic Society of Bengal.
Calcutta, Dec. 22nd, 1932.

appointed Hunterian professor of surgery and pathology, his subject being the variation in distribution of the cerebral arteries. In October, 1909, he was chosen to assist Shattock in selecting, arranging, and cataloguing specimens in the museum to illustrate the main principles of general pathology. His energy, foresight, orderliness, and excellent technique, aided by Shattock's philosophic outlook, completed "for the first time" (to use the words of Sir Arthur Keith) "a work written not in words but in illustrative specimens—a complete and systematic treatise on general pathology." From 1916 onwards Beadles was engaged in arranging and describing the Army medical war collection of pathological and other specimens, work which occupied him, with the help of Mr. T. W. P. Lawrence, until 1921, when the preparations were entrusted by the War Office to the keeping of the College, and are now exhibited as "The Army Medical Collection." These 3000 specimens illustrate from every aspect the injuries and diseases incidental to warfare. The College recognised his services in 1927, when he was elected F.R.C.S. without examination. He was appointed pathological curator when Shattock died in 1925, and from then onwards was engaged in the never-ending task of making a new descriptive catalogue of the pathological specimens in the museum, together with the examination and description of those which are being constantly added.

Sir D'Arcy Power writes: "It may fairly be said of Beadles that he was in the true line of succession of those who have built up the pathological side of the Hunterian museum—Clift, Paget, Doran, Goodhart, Targett, and Shattock. More he would not have wished.

"Somewhat above middle height, clean shaven, with prematurely white hair, and of ascetic appearance, Cecil Beadles was unmarried, and lived for his garden and the Hunterian museum at the Royal College of Surgeons. He was so retiring that he was rarely seen even by his colleagues unless they went to look for him in the workrooms or the museum of the College."

CORRESPONDENCE

THE VALUE OF MASSIVE RADIATION

To the Editor of THE LANCET

SIR,—An agreement with the Radium Commission prohibits members of the Westminster Hospital staff from publishing anything about their work with the four-gramme "bomb," but as my experience of teletherapy antedates, and is not confined to, the use of that unit, I feel at liberty to point out certain implications of the final report of the Conference on Radium (THE LANCET, Jan. 7th, p. 44) that may not be entirely obvious.

The two centres selected by Mr. Souttar as examples of what can be done with teletherapy are both of them free from financial anxiety and entirely independent. They are not subject to any of the restrictions imposed on us at Westminster. Both are free to choose exactly what type of case they will study and treat; both are free to reject any case they consider unsuitable; both of them are free to use the available radium in any form and aggregates they like; neither of them is under an obligation, I believe, to present any report until they so desire; in both centres it is thoroughly understood that, except in restricted fields, radium teletherapy has not yet reached a stage in which it is suited for the routine treatment of a hospital's patients.

No one will be better pleased than I to see a big unit re-established in this country, provided it is under the supreme control of a man of great clinical experience, senior enough to secure harmonious working of his team, and able to devote his whole time to irradiation work. Provided also that there is ample financial support, entire freedom of choice as to the use of the radium—whether for physical and biological research, or for clinical work in any selected field—and provided there is no embargo upon the simultaneous employment of other methods if desired.

I do not think the "bomb" establishment ought to be attached to *any* single hospital. If it be attached to one hospital, workers in other hospitals do not find their way into the wards and laboratories as easily as they should. There is a traditional diffidence as to intrusion. That, certainly, has been our experience. Notwithstanding cordial invitation, and entire liberty of access to every detail of our work, scarcely any London radium workers ever set foot inside the doors of our annexe. I believe that I am right in saying that no member of the Conference on Radium or its technical committee had ever paid a visit of investigation (though some visited individual patients), until after the radium was finally withdrawn from the apparatus. Of specialists from the Empire and from other countries, there were several who thought it worth while to learn what we had to show, and we have spent many days in demonstration and discussion with them.

It is highly desirable that every hospital should coöperate, and that all the brains of the profession —including those of the physicists—should be laid under contribution; but that will not be the case unless the institution selected or built for the proposed five-gramme unit is actually independent of any of the general hospitals, even the post-graduate.

I am, Sir, yours faithfully,

E. ROCK CARLING.

London, W., Jan. 10th, 1933.

FACIAL PALSY AND INFECTION WITH ZOSTER VIRUS

To the Editor of THE LANCET

SIR,—The interesting communication by Dr. Aitken and Dr. Brain in your last issue has suggested to me the publication of the following notes.

A man, aged 39, a cook, was admitted under my care on June 27th, 1932. On June 10th he noticed "pricking" sensations over the left side of the face and temple, followed the same day by reddening of the skin of the lower lip, chin, cheek, and temporal region of the same side, rapidly replaced by patches 1–2 cm. in diameter of closely set papules which two days later had become vesicular. This eruption was associated with some swelling and tenderness of the lingual, submaxillary, and auricular lymph glands. By the end of a week the vesicles had burst and were covered with reddish crusts, the paræsthesia which had disappeared now recurred, and the affected areas of skin were tender to touch; there was also some pain in the tongue and in the ear of the same side, and a minor degree of deafness. On June 22nd, that is to say on the twelfth day after the appearance of the herpes, on wakening in the morning the left side of the face was found to be paralysed.

On admission five days later there were found numerous crusted lesions on the areas above described, with complete loss of sensibility over the same distribution. Examination of the left auditory meatus revealed a few broken vesicles on the walls but the tympanum appeared normal. The

st-graduate Course on Tuberculosis

The Joint Tuberculosis Council have arranged for a t-graduate course to be given at the Brompton Hospital. ndon. from Feb. 20th–25th. Particulars may be had m Dr. William Brand. 8. Highway-court. Beaconsfield, cks.

yal London Ophthalmic Hospital

The annual dinner of past and present students of Moor- ds Hospital will be held at the Langham Hotel. Portland- ace. London. W.. on Thursday. Feb. 9th. at 7 for 7.30 P.M. Arnold Lawson will take the chair. and tickets may be d from Mr. Rupert Scott. 70, Harley-street. W. 1.

itish Institute of Philosophy

Dr. C. S. Myers will take the chair at a meeting to be ld at University College. Gower-street. W.C.. at 8.15 P.M. Tuesday. Jan. 17th. when Prof. F. A. P. Aveling will eak on Some Contemporary Contributions of Psychology Philosophy.

oyal Microscopical Society

A presidential address to this society will be given by r. Conrad Beck in the Hastings Hall of B.M.A. House. vistock-square. London. W.C.. at 5.30 P.M.. on Wednesday. n. 18th. His subject is Microscope Illumination with ansmitted Light.

uild of Public Pharmacists

Mr. Wilfred Trotter. senior surgeon to University College ospital. will address a meeting of this guild at the house the Pharmaceutical Society. 17. Bloomsbury-square. ondon. W.C.. at 7.30 P.M. on Wednesday. Jan. 18th. he title of his address will be De Minimis. Dr. C. H. ampshire. secretary of the Pharmacopœia Commission. ll take the chair.

erman Balneological Society

The forty-eighth German balneological congress will take ace in Baden-Baden from April 4th–8th under the presi- ncy of Prof. Dietrich. of Berlin. The principal subjects r discussion will be the Importance of Diagnosis in Health esort Practice and the Present Position of Climatotherapy. he meetings are open to all interested. and communications ould reach the secretary. Dr. Max Hirsch. Derfflingerstr. 7, erlin. W.35. not later than Feb. 1st. 1933.

ociety of Medical Officers of Health

A meeting of this society will be held at 1, Upper Montague- reet. London. W.C.. at 5 P.M.. on Friday. Jan. 20th. A scussion on What do we really mean by Mental Deficiency? ill be opened by Dr. G. A. Auden. school medical officer r the city of Birmingham, and Dr. F. C. Shrubsall. nior medical officer of the London County Council.—The ntal officers' group will meet at 8 P.M. on Friday. Jan. 27th. hen Mr. D. E. Mason will read a paper on Dentistry and e Dental Officer in the Public Health Services.

pring Medical Congress at Wiesbaden

The forty-fifth meeting of the Deutsche Gesellschaft für nere Medizin is to be held at Wiesbaden from Tuesday. pril 18th. to Friday. the 21st. under the presidency of rof. L. Lichtwitz (Berlin). Tuesday will be devoted to a iscussion on the significance of the heavy metals in physio- gy and pathological processes. with papers by Heubner Berlin). Zangger (Zürich). Martini (Bonn). and Embden Hamburg). On Thursday. three papers on the pathology f the erythrocytes and of hæmoglobin will be given by Hans Fischer (Munich). Kämmerer (Munich). and Seyderhelm Frankfurt). The programme for Wednesday includes a ummarising lecture on the problem of the adrenals. Any ho wish to take part should give notice before Feb. 5th o Prof. Lichtwitz at Rudolf Virchow Krankenhaus. Berlin.

West End Hospital for Nervous Diseases

This hospital offers special facilities for the instruction f post-graduate students in neurological and psychological medicine. The out-patient department at 73. Welbeck- treet. London. W.. has an annual attendance of over 0,000 patients. and the practice of the hospital can be attended by payment of a small fee. Appointments are also vailable as hon. clinical assistants and hon. clinical psycho- ogists. and there is a special clinic with training centre nd a fully equipped child guidance unit associated with the out-patient department. The in-patient department in Regent's Park. containing 76 beds (with a special ward of 5 cots for children), affords opportunities for the study and nvestigation of a wide range of cases. Two courses of ecture demonstrations are arranged annually in conjunction ith the Fellowship of Medicine. and the hospital is also ssociated with Bethlem Royal Hospital in the provision f courses for the diploma of psychological medicine.

History of Plague in England

On Friday. Jan. 20th. at 8.45 P.M.. at the Princess Elizabeth of York Hospital for Children. Shadwell. E.. Col. W. P. MacArthur will give a lantern lecture on Plague in England in Old Times. Visitors are invited.

Devonport Military Hospital

This hospital, built at the end of the eighteenth century. is shortly to be sold by auction by order of the War Office. When. some time ago. it ceased to be used for soldiers wounded in the war it was offered to the corporation of Plymouth on generous terms. but the cost of adapting the buildings to municipal purposes was found to be prohibitive.

Dufferin Hospital for Children, Belfast

An extension of this poor-law hospital. named the "Ava" wing. which has cost £31.500, was opened on Dec. 29th by the Marchioness of Dufferin and Ava. All the wards have purposely been made small for the confinement of infection to a small area. An anæsthetic room has been provided adjoining the theatre.

London School of Hygiene and Tropical Medicine

A course of lectures on some aspects and problems of medical and industrial psychology will be given at this school on Mondays and Wednesdays during the present term. The lecturers will be Prof. Millais Culpin, Mr. Eric Farmer. Prof. Major Greenwood. and Miss May Smith. The first lecture. a historical introduction. will be given by Prof. Greenwood on Jan. 16th at 2 P.M. The course is primarily intended for students taking the diploma in public health or the diploma in industrial psychology of the University of London. but other members of the medical profession or students of the university are invited to attend.

People's League of Health

On Monday next. Jan. 16th. the twelfth annual series of Sims Woodhead memorial lectures. consisting of 13 "constructive educational health lectures." will open at the headquarters of the National Union of Teachers. Hamilton House, Mabledon-place. London. W.C. They will be given on consecutive Mondays at 6 P.M.. and the lecturers will be Dr. K. B. Aikman. Dr. J. S. Fairbairn. Dr. W. J. O'Donovan. Prof. D. F. Fraser-Harris. Prof. S. J. Cowell. Dr. J. Burnett Rae. Sir Leonard Hill. Dr. John Oliver. Dr. Philip Manson-Bahr. Dr. W. G. Willoughby. Dr. J. Sim Wallace. Sir Thomas Oliver. and Sir Frederick Hobday. Particulars may be had from the general secretary of the League at 12. Stratford-place. London. W. 1.

Hospital Libraries

A meeting under the auspices of the London and Home Counties Branch of the Library Association will be held at the Middlesex Hospital nurses' home. Foley-street. W. 1. on Jan. 25th. at 3 P.M. Miss Marian Frost will preside. and short papers will be read by Mrs. R. Beddington and Mrs. Richmond. honorary librarians to the Middlesex and Guy's Hospitals. Dr. W. J. T. Kimber. Mr. C. E. A. Bedwell. house governor. King's College Hospital. and Mr. G. R. Bolton. borough librarian. Watford. An exhibition will be held of methods and stationery. including book labels. employed by the various hospital libraries. Any exhibit that is likely to prove of interest should be sent to Mr. Bolton. Public Library. Watford. before Jan. 21st.

Edinburgh Royal Infirmary

The report for the year ended Sept. 30th last states that it has been necessary to draw upon the invested funds to the extent of £18.726. after utilising all legacies not earmarked for endowment. The deficiency has been met by other legacies and special donations amounting to £19.000. but the managers feel so much anxiety that a committee has been appointed to consider the whole financial position. Almost every item of ordinary income shows a reduction: a conspicuous exception is an increase of over £800 in receipts under the Road Traffic Act. Legacies fell from £75,000 to £56.000. The total of the year's ordinary expenditure was £157.000. a small increase. In-patients numbered 19.145; the daily average under treatment was 980. a fractional increase: at 17·45 there was also a fractional increase in the number of days' stay. Despite all efforts to reduce it the waiting list showed an average during the year of 3057. Out-patients exceeded 66.000. a substantial increment. The cost per occupied bed was £160 5s. 5d. and the average cost per day per patient 8s. 9d. A system of budgeting has been introduced. the expenditure of each department being restricted to a given figure "so far as it is possible to do so and maintain efficiency."

"EPISTAXIS WITHOUT TELANGIECTASIA"

To the Editor of THE LANCET

SIR,—Since Fordyce (1784), Sutton (1864), Babington (1865), Legg (1876), Chiari (1887)—not to mention Frank (1840), Rendu (1896), Osler (1901, 1907, 1911), Kennan (1902), F. Parkes Weber (1907), Goldstein (1921, 1930, 1931, 1932), and many others—reported their cases of heredofamilial bleeding (non-purpuric and non-hæmophilic), epistaxis with and without telangiectasia, a number of interesting papers on this subject have appeared. There are probably recorded to date about 110 or 120 families and about 700 persons suffering from Rendu-Osler-Weber's disease (heredofamilial epistaxis with or without familial hæmorrhagic telangiectasia) in the entire available medical literature of the world. In your issue of Dec. 17th Dr. Eric Wordley reports a family suffering from "epistaxis without telangiectasia." I believe if careful search were made, telangiectases would be found in some members of this family—in the nose, mouth, rectum, or under the finger-nails, on the lips, tongue, palate, conjunctivæ, or somewhere on the body.

I am, Sir, yours faithfully,
HYMAN I. GOLDSTEIN, M.D.

Camden, New Jersey, U.S.A., Dec. 27th, 1932.

DOSAGE OF INSULIN

To the Editor of THE LANCET

SIR,—As a diabetic of moderate severity (40–50 units insulin a day) and a medical man, I should like to emphasise to fellow sufferers, and those who treat them, the importance of not only standardising the diet, but of *stabilising* the dosage of insulin to that diet with each fresh batch of insulin employed. The urine should be tested three-hourly for three days after commencing a batch of insulin, as the alteration of *quantity* (if any) required does not make itself manifest in the urine at once. I, having stabilised my dosage for the batch, make an arrangement with the supplier to put on one side the whole of that batch for my special use.

I would like to quote from "Physiology and Biochemistry in Modern Medicine," by J. J. R. Macleod (6th ed., 1930, p. 919), "The Assay of Insulin." The definition of a unit of insulin as accepted by the Standardisation Committee of the League of Nations is given, and Prof. Macleod makes the following statements:

> "A *latitude* of about *15 per cent. either way* is therefore allowed in the assay of the manufactured product. This fact should be borne in mind by physicians using insulin in the treatment of diabetes, and *in changing from one batch to another, patients should be carefully watched* for a *day or two* to see that the *previous dosage is maintained.*" (The italicising of the words quoted do not appear in the text.)

If I had not fortunately consulted this work I doubt if I should be alive now to write this letter. I believe the latitude allowed in the new British Pharmacopœia in the standardisation of insulin is reduced to 10 per cent., but even if this is so it would still be a very serious matter to a case of true diabetes, and probably would not apply to brands of French or other foreign manufacture.

I am, Sir, yours faithfully,
"A DIABETIC DOCTOR."

Jan. 2nd, 1933.

⁂ Since other variables, such as absorption rate, are so great and food-table values merely approximate, our correspondent seems hardly justified in attributing his continuance in health to the discovery of a 10 or 15 per cent. discrepancy in the potency of his insulin, and it is unlikely that a difference of th order could be appreciated by a patient. The assay of insulin is one of the most accurate of its kind, and to obtain a reproducibility of 10 per cent in a biological method indicates a triumph over technical difficulties. British insulin is, we believe, standardised to as high a degree of accuracy as any insulin in the world.—ED. L.

EPSOM COLLEGE

To the Editor of THE LANCET

SIR,—Having read Dr. Raymond Crawfurd's appeal I have sent him one guinea, in the hope that 499 othe grateful patients will do the same—as they should.

I am, Sir, yours faithfully,
A GRATEFUL PATIENT.

Jan. 7th, 1933.

MEDICAL NEWS

University of London

At recent examinations the following were successful:—

M.D.

Branch I. (Medicine).—J. V. Armstrong and Alison M. Clar St. Mary's Hosp.; F. S. Cliff, Univ. Coll. Hosp; *E Conybeare, Guy's Hosp.; Idris Davies, Cardiff and Westminst Hosp.; W. P. Greenwood, St. Bart.'s Hosp.; G. B. M. Hegg St. Mary's Hosp.; H. B. Hodson, St. Thomas's Hosp; H Howell, London Hosp; Alfred Mitchell, King's Coll Hosp A M. Nussbrecher, Middlesex Hosp.; Nellie H. Reynolds Cambridge and King's Coll Hosp.; Ursula Shelley, Roy Free Hosp [illegible] 's Hosp; H. C. Trowell St T [illegible] J. Vinter, Roy. Free Hosp

Br [illegible] Oakley, Univ. Coll. Hosp, C. G [illegible] K. Simpson, Guy's Hosp, and [illegible] ondon and Guy's Hosps

Br [illegible] *seases of Women)*—Mabel A Baker, Roy. Free Hosp; Kathleen M. D. Harding, Roy Free and St. Mary's Hosps.; Eileen S. Morris, Univ. Coll Hosp *W. C W Nixon, St. Mary's Hosp.; E. M. Shippam, Roy Free Hosp.; and H. J. D. Smythe, Univ. of Bristol and London Hosp.

Branch V. (State Medicine).—A. R. Thompson, London Hosp and London School of Hygiene.

* University medal.

Two lectures on Iodine and the Thyroid Gland will be given in the governors' hall, St. Thomas's Hospital, S E by Dr. Edward Mellanby, professor of pharmacology in the University of Sheffield, at 5 P.M. on Thursday, Jan 26th and Friday, Jan. 27th. The subject of the first lecture at which Prof. John Mellanby will take the chair, is Goitres—Experimental and Clinical, while on Friday the lecturer will speak on Hypo- and Hyper-thyroidism. No ticket is required.

The Out-patient Problem

In a message to King Edward's Hospital Fund for London the Prince of Wales, the president, refers to the report on out-patient departments just issued (THE LANCET, Jan 7th pp. 42 and 51) It will, he says, enable the public to realise how difficult a problem it is, and how many experiments the hospitals themselves have been making to reduce the hours of waiting "But the report," he says, "is more than a mere academic discussion of the question It is meant to lead to action. Its actual recommendations are carefully worded so as to respect the freedom of the individual hospitals, which is an essential feature of the voluntary system. But the committee present a strong prima facie case for believing that part of the waiting time can be reduced, and they want the hospitals to study that case in detail with a view to taking action wherever it is practicable." Accordingly the Prince has appointed a small committee which shall have power not only to consider, in consultation with the hospitals, what steps can be taken, but, in coöperation with the management and distribution committees, to take the necessary steps.

This committee will be called the out-patients' arrangements committee, and will consist of Sir John Rose Bradford consulting physician to University College Hospital (chairman); Dame Rachel Crowdy, R.R.C.; Sir Ernest Morris late house governor of the London Hospital; Sir Isidore Salmon, M.P., chairman of J. Lyons and Co.; Mr. Eric Pearce Gould, surgeon to Middlesex Hospital; Lieut.-Colonel A. P. Irwin, clerk to the governors of St. Thomas's Hospital; and Mr. R. H. P. Orde, hon. secretary of the British Hospitals Association.

NOTES, COMMENTS, AND ABSTRACTS

THE MEDICAL SCHOOLS AND THE NATION'S HEALTH*

BY JAMES YOUNG, D.S.O., M.D., F.R.C.S. EDIN., F.C.O.G.

GYNECOLOGIST TO THE ROYAL INFIRMARY, AND PHYSICIAN TO THE ROYAL MATERNITY HOSPITAL EDINBURGH

(Concluded from p. 63)

The Doctor and the Public

ENOUGH has been said, as I believe, to prove that by the necessities of their development the medical schools have acquired an organisation equipped for the study of disease but ill-devised for the study of health. It is not easy to see how on a tree of such sturdy growth we can engraft a stem of such different lineage. And yet, if we are to take our part as a creative force in the crusade for health, it is clear that this can be done only by some fundamental breach with the past. A complete readjustment of outlook and a profound change in our method are called for. We must be satisfied with no ambition short of one which aims at capturing for our schools and our profession a rôle that is creative and charged with leadership. In the machine of public health the medical profession through its health officers has fulfilled and is fulfilling an important task as policeman, but in the new outlook we must envisage a function of deeper and fuller responsibility.

The apathy of organised medicine towards the positive value of health ideals is a matter of frequent public comment and it has been instrumental in creating a certain estrangement between the laity and the profession, which has been increasingly evident during the past generation. The spread of education, the increased interest being taken in personal and public hygiene, and the opportunities now presented to large numbers of the non-medical public through the health activities of the local authorities to identify themselves with recent progressive movements have all contributed to an increasing appreciation by the community of the extent to which this inertia exists in medical corporations and in medical circles generally. We have quoted instances showing how the lack of the energetic participation of the profession in matters particularly within its concern has resulted in the community being compelled to assume for itself the function of leadership, for example, in regard to the protection of child and maternal life. The same is true of many other health matters. Indeed, to the student of present-day life one of the most remarkable things is this spontaneous and rapid spread of health ambitions and ideals in the nation and the manifold shapes these assume.

In passing we should perhaps point out that the change in the attitude of the public towards the profession has had additional causes. Amongst these probably one of the most significant arises from the fact that the general enlightenment of the public in matters relating to health has brought with it a dawning realisation of the fallibility of the doctor. This is a common topic for raillery in modern literature in which the profession has become a favourite butt of the dramatist and the novelist.

In self-defence we may plead that this affection of omniscience by the medical man has never been truly of his own creation, except in so far as he has allowed himself too rigidly to submit to the convention that it is improper for the doctor to take the public into his confidence through the medium of the press or the platform. The intention underlying this injunction is sound; yet it has undoubtedly contributed to the creation of misunderstanding and it has hindered that identification of the profession with public sentiment and effort that would have been for its good. Further, the peculiar and special nature of our knowledge has tended to make it recondite to the uninitiated; indeed the very language of medicine is in itself a deterrent to a free interchange of ideas as any of us knows who has tried to explain the circumstances of an illness to the friends of the sufferer.

There is another consideration which in the opinion of some has seriously damaged the profession in the eyes of the public and which we cannot afford to overlook. This is the so-called commercialisation of medicine and, more particularly, the commercialisation of the specialties. I do not intend to enter into a discussion of the facts underlying this remarkable innovation in modern medicine for it is not directly germane to the subject of this address and allusion has already been made to it in reference to the circumstances surrounding the recent and rapid development of specialism. We may, however, point out that our so-called charity hospitals, although originally founded solely for the destitute sick, have grown to such an extent that they now serve roughly four-fifths of the community. Their clientèle is now drawn from social strata which are to a large extent economically independent and yet they continue to conduct their work under the old statutes with a medical staff serving on a charity basis. This necessarily implies that the large numbers of the specialists required for their manning, and who receive no payment for their services, must extract their living from the small and the gradually shrinking proportion of the population who remain outside. Viewed in this light the development which has given rise to so much criticism by the public and so much misgiving in the profession is entirely economic in its origin. At the same time it should be pointed out that the specialist services of the large hospitals possess a large number of young men who are necessary for the charity machine, which they serve gratuitously, and who are often living during the best period of their lives in circumstances of great privation. This they tolerate largely because of the consuming interest of the work and partly in the hope of better days to come. Viewed on the average it is probably correct to say that the specialties are the most poorly remunerated section of the profession. It may be argued that much of the gravity of the hospital problem has sprung from the indifference with which the medical profession has allowed itself to be exploited. This is true but in this respect it has been no more culpable than the charitable public at large. Whatever the facts there can be no doubt that the problem alike in its public and its medical aspects can be solved only by a complete revolution in the hospital policy of the country.

I have permitted myself this short digression through a desire to show that the attitude of the public towards the profession has had more than one source, to which we have to direct our attention if we are to rehabilitate ourselves in the life of the nation. It is, however, no exaggeration to say that of these none is so significant as the general lethargy of the doctor in matters of health as distinguished

---

Medical Diary

SOCIETIES

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

TUESDAY, Jan. 17th.—5.30 P.M., GENERAL MEETING OF FELLOWS. 8.30 P.M., PATHOLOGY. Meeting at the Imperial Cancer Research Fund Laboratory, 8, Queen-square, W.C. Demonstrations. L. Savatard (Manchester): Specimens illustrating Intra-epithelial Spread of Carcinoma. J. A. Murray: Spontaneous ? Cure of Cancer. Melanotic Sarcoma of Choroid. Destructive Contribution to the Lymph-stasis hypothesis. W. Cramer and H. G. Crabtree: Effect of Inhibitors of Metabolism on Transplantability of Tumours. L. Foulds: Thymus Metastases of Filtrable Fowl Sarcomata. F. R. Selbie: Growth of Jensen Rat Sarcoma in Susceptible Rats. A. F. Watson: Tar Carcinoma in Rats. Apparatus for the Preparation of Carcinogenic Tars under Standard Conditions.

THURSDAY.—5 P.M., DERMATOLOGY. (Cases at 4 P.M.) Cases. Dr. G. Bamber: 1. Pityriasis Rubra Pilaris. 2. Arsenical Pigmentation and Hyperkeratosis. Other cases will be shown. 8.30 P.M., NEUROLOGY and PSYCHIATRY. Special discussion on the Mental and Physical Symptoms of the Presenile Dementias. Openers: Dr. Macdonald Critchley and Dr. George Riddoch: Neurology. Dr. R. D. Gillespie and Dr. T. R. Hill: Psychiatry.

FRIDAY.—5.30 P.M., PHYSICAL MEDICINE Discussion: Value of Physical Methods in the Treatment of Heart Disease. Openers: Dr. F. G. Thomson, Dr. B. T. Parsons-Smith, Dr. T. F. Cotton, and Dr. Geoffrey Holmes. 8.30 P.M., RADIOLOGY; OBSTETRICS and GYNÆCOLOGY. Special discussion on Radiotherapy in the Treatment of Non-malignant Gynæcological Conditions. Openers: Dr. N. S. Finzi (Radiology); and Mr. Malcolm Donaldson (with Dr. R. Moore Patterson) (Obstetrics and Gynæcology), followed by Dr. F. Hernaman-Johnson and Mr. Norman White.

HUNTERIAN SOCIETY.

MONDAY, Jan. 16th.—9 P.M. (at Cutlers' Hall, Warwick-lane, E.C.), Dr. Einar Thomsen (Copenhagen): Experimental and Clinical Studies of Gastric Juice (Hunterian Lecture).

CHELSEA CLINICAL SOCIETY.

TUESDAY, Jan. 17th.—(At the Hotel Rembrandt, Thurloe-place, S.W.), preceded by a dinner at 7.30 P.M., Discussion to be opened by Dr. H. T. P. Young on Character Defects in Young Delinquents.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE, Manson House, Portland-place, W.

THURSDAY, Jan. 19th.—8.15 P.M., Dr. F. M. Burnet: Recent Work on the Nature of Bacteriophages; and Colonel F. P. Mackie, I.M.S. (ret.): The Technique of Bacteriophage Investigation as Used in India for Cholera and Dysentery.

ROYAL INSTITUTION, 21, Albemarle-street, W.

THURSDAY, Jan. 19th.—5.15 P.M., Prof. J B S. Haldane: Recent Advances in Genetics.

FRIDAY.—9 P.M., Sir William Bragg: The Crystals of the Living Body.

TUBERCULOSIS ASSOCIATION.

FRIDAY, Jan. 20th.—5.15 P.M. (at the London School of Hygiene, Keppel-street, W.C.), Prof. S. Lyle Cummins: Tuberculosis and the South African Native. 8.15 P.M., Dr. Philip Ellman: Pulmonary Asbestosis, Its Clinical Pathological, and Radiological Aspects, and Tuberculosis Risk.

SOCIETY OF MEDICAL OFFICERS OF HEALTH, Upper Montague-street, W.C.

FRIDAY, Jan. 20th.—5 P.M., Dr. G. A. Auden and Dr. F. C. Shrubsall: What do we mean by Mental Deficiency?

NORTH LONDON MEDICAL AND CHIRURGICAL SOCIETY, Royal Northern Hospital, N.

FRIDAY, Jan. 20th.—9 P.M., Mr. Kenneth Walker: Ourselves and Our Critics.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Jan. 16th, to SATURDAY, Jan. 21st.—NATIONAL HEART HOSPITAL, Westmoreland-street, W. Special Post-graduates Course in Cardiology. All day.

TUESDAY.—4 P.M., MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square. Lecture on Views on the Ætiology and Treatment of Peptic Ulcer, by Dr. Daniel T. Davies. (Free to Members and Associates.)

FRIDAY.—4.30 P.M. to 6 P.M., Demonstration of X ray Films of the Chest, Heart, and Intestinal Tract, by Dr. Peter Kerley. (Especially suitable to M.R.C.P. candidates.)

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, [illegible] W.

[illegible] M., Medical Wards, Skin Dept., [illegible] ns. 2 P.M., Medical, Surgical, Out-patients, Surgical Wards, [illegible] Lecture, Mr. Sinclair: Acute Appendicitis.

TUESDAY.—10 A.M., Medical Wards, Surgical Demonstration. 2 P.M., Medical, Surgical, Throat, Nose, and Ear [illegible] Operations. 4.15 P.M., Lecture, Dr. H. [illegible] Infections.

[illegible] Medical Wards, Children's Out- [illegible] Medical, Surgical, and Eye Out-patients.

THURSDAY.—10 A.M., Neurological Department, Fracture Demonstration. 2 P.M., Medical, Surgical, Eye, and Genito-urinary Out-patients. 4.15 P.M., Lecture Mr. Tyrrell Gray: Surgical Disorders of the Viscera.

FRIDAY.—10 A.M., Skin Department. 12 noon, Lecture: Therapeutics. 2 P.M., Medical, Surgical, and Throat Out-patients. Operations.

SATURDAY.—10 A.M., Throat Operations, Medical and Surgical Wards. Surgical and Children's Out-patients. The lectures at 4.15 P.M. are open to all Medical Practitioners without fee.

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, Denmark-hill, S.E.

THURSDAY, Jan. 19th.—9 P.M., Dr. H. A. Lucas: Hay Fever and Allied Conditions.

ROYAL NORTHERN HOSPITAL, Holloway-road, N.

TUESDAY, Jan. 17th.—3.15 P.M., Dr. E. G. B. Calvert: Modern Aids in Digestive Disorders.

ST. MARK'S HOSPITAL, City-road, E.C.

THURSDAY, Jan. 19th.—4 P.M., Mr. W. B. Gabriel: Appendicostomy: Indications, Technique, and Management.

LONDON JEWISH HOSPITAL, Stepney Green, E.

THURSDAY, Jan. 19th.—4 P.M., Dr. M. Schwartzman: X Ray Demonstration.

PRINCESS ELIZABETH OF YORK HOSPITAL, SHADWELL, E.

WEDNESDAY, Jan. 18th.—3.30 P.M., Prof. Leonard Findlay: Demonstration on Chorea.

CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn-road, W.C.

FRIDAY, Jan. 20th.—4 P.M., Mr. J. D. McLaggan: Giddiness.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital 49, Leicester-square, W.C.

TUESDAY, Jan. 17th.—5 P.M., Dr. G. B. Dowling: Seborrhœa. Seborrhœic Dermatitis.

THURSDAY.—3 P.M., Dr. I. Muende: Pathology Demonstration.

GLASGOW POST-GRADUATE LECTURES.

WEDNESDAY, Jan. 18th.—4.15 P.M. (at the Royal Maternity and Women's Hospital), Dr. S. J. Cameron: Obstetrical Cases.

Appointments

DODDS, R. L., M.B., M.Ch., B.A.O., F.R.C.S. Eng., has been appointed Assistant Obstetric Surgeon, City of London Maternity Hospital.

Certifying Surgeons under the Factory and Workshop Acts: DAVIES, H. G., L.R.C.P. Lond., M.R.C.S. (Llanid Montgomery); SQUIRES, F. V., M.B., Ch.B. Camb. (Wantage, Berkshire).

Births, Marriages, and Deaths

BIRTHS

BARNES.—On Jan. 8th, at Welbeck-street, W., the wife of F. G. L. Barnes, M.B., B.S. Lond., of Horton, Epsom, of a son.

BERTRAM.—On Jan. 7th, at a nursing home, the wife of Surg.-Lieut. D. Bertram, R.N., of "Gwynt," Wraxall, Bristol, of a son.

COLLYNS.—On Jan. 2nd, at Dulverton, the wife of Dr. P. C. Collyns, of a daughter.

GREEN.—On Jan. 8th, at Bromley Common, Kent, the wife of Dr. H. F. Green, of a son.

MILLER.—On Jan. 3rd, at Moniaive, St. Lawrence, the wife of Dr. A. K. Miller, of a son.

MARRIAGES

LOCKHART-MUMMERY—POLAK.—On New Year's Eve, 1932, quietly, in London, John Percy Lockhart-Mummery, F.R.C.S., of Harley-street, to Madame Georgette Polak, of Clive Court.

PRICE—STEVENS.—On Jan. 7th, at Holy Trinity Church, Brompton, Major Robert Bernard Price, R.A.M.C., to Daphne, only daughter of Mr. H. Stevens, of Herne Bay.

DEATHS

BEADLES.—On Jan. 3rd, at Gresham House, Egham Hill, Cecil Fowler Beadles, F.R.C.S., Pathological Curator, R.C.S. Eng., aged 66.

DONALDSON.—On Jan. 3rd, at Bridgford, Woodside-avenue, Muswell-hill, N., Prof. Robert Donaldson, M.A., M.D., F.R.C.S., aged 55.

HAMILTON.—On Jan. 7th, at Sutherland-avenue, Bexhill-on-Sea, George Hamilton, M.B., B.S.

MENZIES.—On Dec. 25th, at 25, Essendine-road, Maida Vale, W.9, James Menzies, M.B., B.S., M.R.C.S., L.R.C.P., eldest son of the late Dr. Duncan Menzies and Mrs. Menzies, aged 16 years.

PRICE.—On Jan. 4th, at Haydown, Amport, Hants, He Bankes Price, J.P., M.R.C.S., L.R.C.P., aged 67.

TYRRELL.—On Jan. 1st, at Kensington-mansions, S.W., Fran Astley Cooper Tyrrell, M.B., B.Ch. Camb., F.R.C.S. Ophthalmic Surgeon, aged 62.

WADDELOW.—On Jan. 3rd, at Whittlesey, near Peterborough, after a short illness, John Joseph Waddelow, F.R.C.S., J.P., in his 65th year.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

us the six-month period has a long run. The 08 Act directed every Maternity and Child Welfare thority to provide for the administration of the t and. where children were kept for reward. to point Infant Protection Visitors. In future one such Visitors must be a woman. and the Visitors e not only to satisfy themselves (and to give cessary advice and directions) as to the proper rsing and maintenance of the infants. but also to their health and well-being. The 1908 Act lowed the Authority to limit the number of children der 7 years old kept in any one house. The new ct substitutes the power to fix the maximum mber of children under 9 years old who may be pt in any dwelling where there is a notifiable ild; in addition. the Authority may impose nditions to be complied with. so long as the number ceeds a specified maximum. Formerly children pt by unfit persons or in unfit premises could be moved on a justice's or a local authority's order. future this will normally be done on a magisterial der obtained on complaint by a local authority. here is power to prevent the reception of a child s well as to remove it. This power operates not ly in the former conditions (if the premises are vercrowded. insanitary. or dangerous) but also if e infant is to be received or kept "in an environent which is detrimental." The grounds of unfitness the person who keeps a child for reward will clude. in addition to negligence. ignorance. inebriety. nmorality. and criminal conduct as before. old age. firmity, and ill-health. There is a new prohibition f anonymous advertisements offering to take charge f children under nine. And there is a more exact tatement of the hospitals. homes. and institutions xempt from the foregoing provisions. These exemptions are now limited to a hospital. convalescent ome. or institution (*a*) maintained by a Government epartment, local authority. or any other authority r body constituted by a special Act or Charter; b) exempted by certificate of the local authority;) voluntary homes supervised by the Home ffice; and (*d*) institutions. houses, or homes ertified or approved by the Board of Control nder the Mental Deficiency Acts in which there re no children or no persons who are not mental lefectives.

It will be appreciated that Part V. of the 1932 ct is merely that part with which the Minister of ealth is mainly concerned. The other Parts of hat is really a Home Office measure deal with uvenile courts, the trial of children, their criminal esponsibility. and their commitment to the care of t persons or to "approved schools," which will oon replace what we formerly knew as reformatory nd industrial schools. There are also new provisions s to juvenile employment. the notification. inspection, nd control of voluntary homes. probation. the nonssociation of juveniles with adults in police stations r criminal courts, and the suppression of young ersons' names. addresses or schools. or their pictures r other particulars of identity. where they are oncerned in proceedings in court or as witnesses. ost of these provisions are not yet in force.

THE K.D. AIR DRYER

THIS preparation is designed to remove moisture rom the normal air. The crystals are supplied in a etal box with a perforated lid which has a central lass window through which the crystals can be seen. ormally the crystals are dark blue in colour, but hen they become charged with moisture. so that hey will absorb no further water from the air, they urn pinkish. The air dryer should then be heated a moderate oven for one and a half hours, when the rystals will recover their original dark blue colour, nd be ready for further use in wardrobes, linen upboards, and other receptacles where rust and ould may do harm in the presence of a moist tmosphere. The invention is put upon the market y Elmesan (London). Ltd., 66. Victoria-street, .W.

THE PATIENT'S POINT OF VIEW

IN his latest commentary on yesterday, to-day. and to-morrow.[1] Mr. Stephen Leacock does not spare the medical profession. In the old days. he remarks. the doctor never talked medicine to the patient. Sometimes he suspected serious illness. but he never said so until recovery was complete; and though the therapeutic methods of those unscientific times may have been limited the practice of medicine was human. gracious. and kindly. "To-day," he says, "it is replaced by 'machine medicine' with the mechanical test. the scientific diagnosis. the hospital, the X ray. All this is marvellous. But no one has yet combined it with the Art of Healing."

The patient of to-day, Mr. Leacock thinks, is regarded by the profession merely as a contraption.

> "The Contraption sits huddled up in its serge suit in a consultation office chair. Its locomotive apparatus is doubled up beneath it, folded at the joints. The thing is anxious, but the doctor doesn't know that. The poor Contraption is consumed with something like panic that is gripping it by the feed-pipe. But it makes as brave a show as it can."

The doctor makes a running commentary on his investigations. "I don't know that I quite like that heart" . . . and "there are symptoms there that I don't like—don't like at all." (Neither does the Contraption, but he keeps quiet.) After further audible reflections on possibilities and probabilities he begins to write on little bits of paper. "Well." he observes. in cheering tones, "we'll try it out anyway."

> "And above all." concludes the doctor with a sudden burst of geniality that he had forgotten to use sooner, "don't worry. You may blow up at any time, but don't let that worry you. You may fall dead in a taxi, but I'm not alarmed if you do. Come back in a week and I'll show you the X ray plates. Good-bye."

After a week—168 hours, or 1080 minutes. or 64.800 seconds—the patient comes back to find his adviser beaming with interest. There is a misty-looking spot in the radiogram of the brain.

> "What is it?" asks the Contraption.
>
> "I don't know yet," the doctor says. "it's a little early to say. But we'll watch it. If you don't mind. I think we'll probably open your head and take a look. They are doing some wonderful things now in the removal of the brain. It's rather a nice operation. but I think I may take the risk. I'll let you know. Meantime you're following out our instructions. I hope—not eating anything?"
>
> "Oh no."
>
> "And nothing to drink or smoke?"
>
> "Oh no."
>
> "That's right. Well. now. in a day or two we'll know more. I'll have your blood by that time and the sections of your heart and then I think we'll begin to see where we are. Good-bye."

To learn the end of this illuminating story. readers will do well to consult Mr. Leacock's book.

A DIRECTORY OF MASSAGE

WE have received a Directory (dated August, 1932) of the Private Practitioners' Association. which is made up of members of the Chartered Society of Massage and Medical Gymnastics who are in private practice. Every entry in the Directory is of one who has qualified in massage and is registered with the C.S.M.M.G., while he may hold additional qualifications from this society, indicated by the appropriate letter. or the diploma of biophysical assistant from the Society of Apothecaries. A number of members are blind ex-Service men. trained at St. Dunstan's. It is also stated whether the member is willing to undertake National Health cases. The Directory is now arranged on an alphabetical basis of towns which makes it easy of reference. A copy will be sent post free to any medical practitioner on application to the hon. secretary of the Association, Mr. J. Stewart Brown. Hygeia. Falmouth.

[1] Afternoons in Utopia. By Stephen Leacock. London: John Lane, the Bodley Head, Ltd. 1932. Pp. 240. 5s.

from his preoccupation with matters of disease. From this it has happened that there is being born in modern life much praiseworthy enterprise in health with which the doctor might have been identified to the advantage both of the nation and of himself, and largely in consequence of his failure to inspire and guide there have sprung into being movements of a quite different order in that, although often sincere in their ambitions and their claims, they are dangerous because they have allowed themselves to become dominated by obscurantism and prejudice.

Back to Hippocrates

What, then, must we do to assert ourselves and to take that place in the health affairs of the nation which belongs to us alike by prescription and by responsibility ? We have seen that devotion to disease has blinded us to the duties of health. We have failed to realise that the school of health is as essential as the school of disease. We have professors of disease. We must have professors of health.

I think I could easily persuade you that we must have in the forefront of our crusade the great fact of nutrition. Indeed, we must urge that this should become a dominating concern of every medical school at the earliest possible moment. Our professor of nutrition will inspire the rising generations of doctors with their larger duties to the public. Within his purview will come the child before and after birth, the observance of boyhood and girlhood and the adult in his various activities of relaxation, industry, and old age. Fresh air and sunshine and exercise will be his concern. He will be interested in the diets of different nations and their relative advantages. He will from his position of authority fulminate against the national peril inherent in our present milk-supplies.

We shall have a professor of public welfare in addition to our professor of nutrition. His special study will be those other factors in the community which are concerned with the safeguarding of the health of the worker, housing, hours of labour, industrial fatigue, &c. At Edinburgh University we have a professor of animal breeding. It has been well said that we bring all the resources of science to bear on the breeding and feeding of our pigs and have forgotten our men. Our professor will have within his ambit the great facts of heredity as these concern the welfare of man.

It is obvious at the outset that our curricula as at present organised cannot find room for the big new demands which we make on the teaching bodies. To objections on this score we can represent that the time has arrived in the history of medical teaching when it is essential that the conceptions responsible for the creation and perpetuation of the present curriculum should be completely revised. The curriculum which squeezes out instruction in such a vital subject as midwifery because of lack of space and yet which includes botany has surely outgrown its period of usefulness. The truth is that, as is now generally conceded, the time is over-ripe for a recasting of our methods of teaching to bring them into line with modern needs. In our approach to this admittedly complex subject our first duty is not a cheeseparing policy of hours here and hours there, but a consideration of the fundamental principles which must guide us towards the creation of a system that is in harmony with modern progress and that will embody and inspire our ideals of future development. Of a surety where our fathers faltered in ignorance we shall fail in the clear light of knowledge if we do not bend all our energies towards infusing the new system with the vision of a great profession dedicated to the service of health.

After assuring ourselves that by such means we have brought the schools into relation with the significance of health as a positive ideal immediately within their concern, we shall have gained much in a reorientation of medical thought and endeavour. We shall have done much to commit organised medicine to the view that the safeguarding of national health is at least as much its responsibility as the palliation of individual disease. Medical conscience, in its broadened outlook, will come more and more to regard disease in its many incapacitating forms not so much as lesions of individual organs each with its own ætiology, but in the main as a symbol of wrong living expressible in terms of nutrition or environment. It will find itself becoming more and more concerned with large matters of economic and social welfare, such as the housing, the feeding, and the work of the people and less with the bottle of medicine and the advice felt to be futile before it is uttered.

The new outlook must break completely with the traditional attitude that health merely represents disease that is prevented, the negative conception which is often found to dominate the utterances of members of organised medicine and which finds expression in the term "preventive medicine" as this is usually understood. The new conception must carry with it a robust conviction of positive virtue. The exponents of disease in their attempts at preventive medicine seek backwards from the morbidly deranged organ for a causation which becomes often more and more elusive the more intensely the search is pursued. The exponents of health look ever forward with a knowledge that the more clearly the principles of health are perceived and the more efficiently they are practised the more does the organism become attuned as a whole to its environment and the more irrelevant does the consideration of any one organ become. So long as the body is healthy the health of its parts is assured. After many long centuries during which it has strayed from the path first clearly perceived by the father of medicine our school will again be dedicated to the great classic ideal of health. Turning back to recapture the spirit of its youth it will inspire a renaissance in the principles of healthy living. *Mens sana in corpore sano—Floreat res medica.*

INFANT LIFE PROTECTION

NEW PROCEDURE IN FORCE

THE coming into operation on Jan. 1st of Part V. of the Children and Young Persons Act, 1932, tightens up the Infant Life Protection provisions of the 1908 Act in many respects. The previous law against baby-farming made it necessary to notify the keeping of children under the age of 7 for reward; the age is now raised to 9. Formerly notice was required within a certain period after reception; now it must be given in advance. Change of address must also be notified in advance, and notice of the death or transfer of the child must be given not only *to the local authority* but *also to the person from whom* it was received for reward. The old law exempted the keeping of children for less than 48 hours; this exemption is now cancelled. The contents of the notice are slightly amplified and there is a somewhat wider definition of "undertaking for reward." The old law allowed a time limit of six months for prosecution for failure to notify. This period was interpreted as running from the first day of failure; naturally, as the omission was often not discovered in six months, many prosecutions broke down. In future failure to notify is a continuing offence;

us the six-month period has a long run. The 08 Act directed every Maternity and Child Welfare uthority to provide for the administration of the t and. where children were kept for reward. to point Infant Protection Visitors. In future one such Visitors must be a woman. and the Visitors e not only to satisfy themselves (and to give cessary advice and directions) as to the proper ursing and maintenance of the infants, but also to their health and well-being. The 1908 Act lowed the Authority to limit the number of children nder 7 years old kept in any one house. The new ct substitutes the power to fix the maximum umber of children under 9 years old who may be pt in any dwelling where there is a notifiable ild; in addition. the Authority may impose nditions to be complied with. so long as the number ceeds a specified maximum. Formerly children ept by unfit persons or in unfit premises could be moved on a justice's or a local authority's order. n future this will normally be done on a magisterial der obtained on complaint by a local authority. here is power to prevent the reception of a child s well as to remove it. This power operates not ly in the former conditions (if the premises are vercrowded. insanitary. or dangerous) but also if e infant is to be received or kept "in an environ-ent which is detrimental." The grounds of unfitness n the person who keeps a child for reward will nclude. in addition to negligence. ignorance. inebriety. mmorality. and criminal conduct as before. old age. nfirmity, and ill-health. There is a new prohibition f anonymous advertisements offering to take charge f children under nine. And there is a more exact tatement of the hospitals. homes, and institutions xempt from the foregoing provisions. These exemp-ons are now limited to a hospital, convalescent ome, or institution (*a*) maintained by a Government epartment. local authority. or any other authority r body constituted by a special Act or Charter; b) exempted by certificate of the local authority;) voluntary homes supervised by the Home ffice; and (*d*) institutions. houses. or homes ertified or approved by the Board of Control nder the Mental Deficiency Acts in which there re no children or no persons who are not mental efectives.

It will be appreciated that Part V. of the 1932 ct is merely that part with which the Minister of ealth is mainly concerned. The other Parts of hat is really a Home Office measure deal with uvenile courts. the trial of children, their criminal esponsibility. and their commitment to the care of t persons or to "approved schools," which will oon replace what we formerly knew as reformatory nd industrial schools. There are also new provisions s to juvenile employment. the notification. inspection. nd control of voluntary homes. probation. the non-ssociation of juveniles with adults in police stations r criminal courts. and the suppression of young ersons' names. addresses or schools. or their pictures r other particulars of identity. where they are oncerned in proceedings in court or as witnesses. ost of these provisions are not yet in force.

THE K.D. AIR DRYER

THIS preparation is designed to remove moisture rom the normal air. The crystals are supplied in a etal box with a perforated lid which has a central lass window through which the crystals can be seen. ormally the crystals are dark blue in colour. but hen they become charged with moisture. so that hey will absorb no further water from the air. they urn pinkish. The air dryer should then be heated n a moderate oven for one and a half hours. when the rystals will recover their original dark blue colour. nd be ready for further use in wardrobes. linen upboards, and other receptacles where rust and ould may do harm in the presence of a moist tmosphere. The invention is put upon the market y Elmesan (London), Ltd., 66, Victoria-street, .W.

THE PATIENT'S POINT OF VIEW

IN his latest commentary on yesterday, to-day. and to-morrow,[1] Mr. Stephen Leacock does not spare the medical profession. In the old days, he remarks, the doctor never talked medicine to the patient. Sometimes he suspected serious illness. but he never said so until recovery was complete; and though the therapeutic methods of those unscientific times may have been limited the practice of medicine was human. gracious. and kindly. "To-day." he says, "it is replaced by 'machine medicine' with the mechanical test. the scientific diagnosis. the hospital, the X ray. All this is marvellous. But no one has yet combined it with the Art of Healing."

The patient of to-day. Mr. Leacock thinks. is regarded by the profession merely as a contraption.

> "The Contraption sits huddled up in its serge suit in a consultation office chair. Its locomotive apparatus is doubled up beneath it, folded at the joints. The thing is anxious, but the doctor doesn't know that. The poor Contraption is consumed with something like panic that is gripping it by the feed-pipe. But it makes as brave a show as it can."

The doctor makes a running commentary on his investigations. "I don't know that I quite like that heart" . . . and "there are symptoms there that I don't like—don't like at all." (Neither does the Contraption, but he keeps quiet.) After further audible reflections on possibilities and probabilities he begins to write on little bits of paper. "Well." he observes, in cheering tones. "we'll try it out anyway."

> "And above all," concludes the doctor with a sudden burst of geniality that he had forgotten to use sooner. "don't worry. You may blow up at any time, but don't let that worry you. You may fall dead in a taxi. but I'm not alarmed if you do. Come back in a week and I'll show you the X ray plates. Good-bye."

After a week—168 hours. or 1080 minutes. or 64.800 seconds—the patient comes back to find his adviser beaming with interest. There is a misty-looking spot in the radiogram of the brain.

> "What is it?" asks the Contraption.
>
> "I don't know yet," the doctor says. "it's a little early to say. But we'll watch it. If you don't mind. I think we'll probably open your head and take a look. They are doing some wonderful things now in the removal of the brain. It's rather a nice operation. but I think I may take the risk. I'll let you know. Meantime you're following out our instructions. I hope—not eating anything?"
>
> "Oh no."
>
> "And nothing to drink or smoke?"
>
> "Oh no."
>
> "That's right. Well. now. in a day or two we'll know more. I'll have your blood by that time and the sections of your heart and then I think we'll begin to see where we are. Good-bye."

To learn the end of this illuminating story. readers will do well to consult Mr. Leacock's book.

A DIRECTORY OF MASSAGE

WE have received a Directory (dated August. 1932) of the Private Practitioners' Association. which is made up of members of the Chartered Society of Massage and Medical Gymnastics who are in private practice. Every entry in the Directory is of one who has qualified in massage and is registered with the C.S.M.M.G., while he may hold additional qualifications from this society. indicated by the appropriate letter. or the diploma of biophysical assistant from the Society of Apothecaries. A number of members are blind ex-Service men, trained at St. Dunstan's. It is also stated whether the member is willing to undertake National Health cases. The Directory is now arranged on an alphabetical basis of towns which makes it easy of reference. [1] Afternoons in Utopia. By Stephen Leacock. London: John Lane, the Bodley Head, Ltd. 1932. Pp. 240. 5s.

SIGHT-SAVING CLASSES

The provision of instruction for partially blind children was the main topic discussed at the annual meeting of the International Association for the Prevention of Blindness, held in Paris last month. The organisation of sight-saving classes and schools in England, America, and Germany was outlined; representatives of Switzerland and France, though they were able to record the existence of schools respectively in Zurich and Basle, and in Strasbourg and Paris, emphasised the need for multiplying classes in other towns in their countries. It was agreed that the special educational methods used in sight-saving classes produce results far superior to those which follow the attendance of partially blind children at ordinary schools.

THE WELSH NATIONAL SCHOOL OF MEDICINE

The stability of the Welsh National School of Medicine between the conflicting claims for its government has long seemed so uncertain that we welcome the confirmation of its present assured position in its first annual report. The compromise arrived at, which was embodied in a charter issued on July 1st, 1931, is that the school is recognised as a separate institution in the Federal University of Wales, and provides instruction in the clinical years of the curriculum. The preliminary sciences (first year) are taught in all four colleges of the university; most of the students, however, study these at the University College of South Wales and Monmouthshire at Cardiff. Second and third year subjects—anatomy, physiology, and organic chemistry—are taught only at this college. The medical students studying at Cardiff during their preclinical years work under the control of a joint academic committee of the college and school, over which committee the provost of the school presides. The entry of first year medical students has increased during the last four years from 28 in the session 1928–29 to 72 in the session 1931–32. It is noted that the resources of the preliminary science department together with those of anatomy and physiology are becoming insufficient to cope with the increased numbers, and unless these resources can be extended limitation of entry will be unavoidable. A valuable addition to the clinical material available for teaching has been the provision of 70 medical beds at the City Lodge Hospital of the Cardiff Corporation.

THE BREATH OF LIFE

We have been asked to review a little book with this title which can be obtained for 1*s*. 6*d*. through Messrs. Simpkin Marshall; it is written by Arthur Lovell, who, we learn, is the author of, among other works, "Volo or the Will" and "Ars Vivendi," and the inventor of a new method of breathing of which he says, "Physically it is the key to health," "Mentally it is the royal road to learning," and "Spiritually it promotes character, self-confidence, and aspiration for good." The inventor seems to have acquired, whether by reformed or deformed breathing, a certain measure of self-confidence. It may be that the medical profession exhibit astonishing ignorance on the subject of breathing and that "Mr. Emil Behnke" (whoever he may be) has been equally reprehensible; but we cannot subscribe to the view that the diaphragm is "the real core of vitality," nor advise the expenditure of 1*s*. 6*d*. on the book.

Vacancies

The Home Secretary is also considering the appointment of a Physician as Medical Referee under the Workmen's Compensation Act, for the Liverpool County Court District (Circuit No. 6). Applications from Physicians for the post should be addressed to the Private Secretary, Home Office, and should reach him not later than Jan. 28th.

The Chief Inspector of Factories announces vacant appointments for Certifying Factory Surgeons at Rothes (Moray), and Northampton (Northampton).

ADDRESSES AND ORIGINAL ARTICLES

MIGRAINE *

By MACDONALD CRITCHLEY, M.D. BRIST.,
F.R.C.P. LOND.
SENIOR NEUROLOGIST AT KING'S COLLEGE HOSPITAL; ASSISTANT PHYSICIAN TO THE NATIONAL HOSPITAL, QUEEN-SQUARE, LONDON

AND

FERGUS R. FERGUSON, M.D. MANCH.,
M.R.C.P. LOND., D.P.H.
ASSISTANT PHYSICIAN TO THE MANCHESTER ROYAL INFIRMARY; DEMONSTRATOR IN SYSTEMATIC MEDICINE IN THE UNIVERSITY OF MANCHESTER

MIGRAINE constitutes one of the most disabling of common maladies; but despite a vast amount of interest in the subject, we are still uncertain about its pathology, its nature, and its cure. Yet migraine has been the happy hunting-ground of the theorist, and the problem has been attacked by representatives of all branches of medicine. Each in turn has discovered in migraine phenomena pertaining to his own specialty; each in turn has hit upon the true nature of the malady; in turn, each has found the infallible remedy. Obviously, such mutually exclusive viewpoints cannot all be entirely correct, and the multiplicity and diversity of the hypotheses suggest that the problem is more complex than imagined, and probably one which presents a number of facets.

That the problem is many-sided is suggested by the wealth of the clinical aspect. In fact, one of the usual errors in describing and explaining migraine is to ignore the less typical though common forms which the malady may offer. It will be necessary at the outset to contrast the usual text-book account of the migrainous phenomena with the manifestations as they actually occur.

What is Migraine?

According to the common description, migraine is a paroxysmal affection comprising severe unilateral headache, preceded by visual phenomena and followed by nausea and vomiting. Undoubtedly, this account is sufficiently accurate to enable a large number of cases to be recognised, but it gives no hint of the occurrence of a far greater number of slighter and incomplete forms, nor of the rarer severe and even catastrophic manifestations. Detailed study of migrainous subjects reveals clearly that attacks may differ in degree and complexity in the same person; and with advancing years, as everyone knows, the attacks may alter and eventually cease to correspond with the classical description of the disease. Nevertheless, these slighter attacks must surely be merely variants of "ordinary" migraine.

Acting upon such clinical data, we may state that *any one of the classical symptoms* (teichopsia, headache, and vomiting) *may be absent.*

Migraine without visual phenomena is, of course, well known, but it is doubtful whether the frequency of such is appreciated. Out of Elliot's series of 300 cases, 18 per cent. complained of hemianopia and 25 per cent. of zigzags or fortification signs. Other alarming visual troubles were noted in 44 per cent., but some of these overlapped the figure for the two previous items. Our figures suggest that visual phenomena are even rarer, and it is possible that the percentages in Elliot's cases are higher because of the nature of the author's practice and experience. It must also be remembered that a large number of patients wake with a migrainous headache, and the visual excitation might have occurred during the sleeping hours.

Certainly nausea and vomiting are often absent, even though headache and visual symptoms are marked. In Elliot's series no nausea and vomiting occurred in one-quarter of the cases. Again, we would suggest that this proportion is too low.

Lastly, in a few instances, headache itself may be in abeyance. This is admittedly rare, and might legitimately cause diagnostic argument, were we not mindful of the occasional absence of headache in the elderly migrainous subject. Under treatment, moreover, the headache may be cured but not the other phenomena.

Advancing our argument further, we may even state that *any two of the classical symptoms may be absent*, and yet the diagnosis of migraine remains. Thus visual phenomena and vomiting may both be absent, the migraine attack being represented by headache alone. Cases of this type are, indeed, common. It may be asked how in such circumstances the diagnosis is made. The character of the headache itself is not without significance, and some of the accompanying disorders, such as confusion, irritability, anorexia, giddiness, photophobia, inability to "carry on," are features which distinguish it from other types of headache. A headache which leads to drowsiness and sleep is suggestive of migraine. The occasional occurrence of other phenomena—teichopsia or vomiting—during one of the patient's usual headaches also indicates the migrainous nature. One may summarise by stating that migraine is the commonest cause of severe periodic headaches, accompanied by prostration—especially if present in the early morning on waking.

If we grant that headache alone may represent a not uncommon type of migraine, we must also admit that vomiting alone and visual phenomena alone are both rare types of migraine. Again, diagnosis may be disputed here, but the periodic occurrence of visual symptoms alone in a migrainous subject is highly suggestive of an abortive attack. Bouts of vomiting alone may occur in younger subjects prior to the development of the complete forms of migraine, and also in the migrainous subject during pregnancy. For these and other reasons we affirm that attacks of vomiting alone may constitute a *forme fruste* of a migraine attack.

Characteristics of the Attack

It will be unnecessary to recapitulate the well-known features of the attack of migraine and to describe the various types of visual disorder which may be experienced. More useful perhaps would be a bare statement of some of the clinical points which are so striking as to demand an explanation in any hypothesis which may be advanced concerning migraine; and, furthermore, a correction of certain incorrect or exaggerated statements commonly made.

(1) *The headache is often not unilateral.* Although this statement challenges the very name of the malady, nevertheless careful introspection reveals that in a high proportion (perhaps even 50 per cent.) the pain does not strictly concern one-half the head.

---

* The opening paper at a discussion at the Harveian Society on Dec. 8th, 1932.

The pain may be more intense on one side, without, however, any strict unilaterality. Pain may be noted in the frontal, parietal, or occipital regions; it may affect the summit of the skull; may occur in the temples or may be referred to one or both orbits. The location of the pain often varies from one attack to another in the same subject.

(2) *Attacks of migraine usually commence in youth and alter or diminish in intensity with advancing years, and may even cease altogether.* The general truth of this statement must not deceive one as to the rarer instances of true migraine appearing in childhood, and even commencing in middle life or old age. One hears at times that migraine ceases with the climacteric; this statement is not altogether correct. Actually the migrainous patient suffers an exacerbation at the menopause, and may continue to suffer alarming attacks for some time afterwards.

(3) The duration of the average attack of migraine, from the commencement of the visual symptoms to the disappearance of the headache, is a matter of some hours. One must remember that *unusually short and unusually long attacks may occur.* Thus we have known patients whose attacks from start to finish do not exceed 15 minutes. On the other hand, severe attacks of migraine may persist for a week, at the end of which the patient may be debilitated, exhausted, and irritable for another six or seven days.

(4) *Vomiting does not necessarily relieve the headache.* Despite statements to the contrary, we can definitely affirm that it is rather exceptional for an attack of migraine to be concluded, or the headache relieved, by the act of vomiting.

(5) *Migraine usually ceases during pregnancy.* This important statement holds true for the great majority of cases. The course of the pregnancy, however, is usually complicated by excessive vomiting.

Clinical Types of Migraine

When one reviews the symptomatology of a large series of cases of migraine, one is struck with certain broad similarities as well as with certain individual differences. The former constitute the general points of contact which make up our conceptions of migraine as a clinical entity. The individual features, however, are both interesting and important. When collected and sifted, they can be arranged into groups, each containing certain combinations of peculiar features. In this way we can isolate certain clinical subgroups, the ætiological and therapeutic significance of which are suggestive.

(1) *The bilious type.*—A type will emerge in which persistent vomiting dominates the picture. Ocular disturbance is slight or absent; headache is present but not severe. The vomiting is obstinate and may last three or four days; food is refused; collapse, loss of weight, and acidosis are often present towards the end of the attack. At times a slight icteroid tinge may be noticeable in the conjunctivæ; the patient may complain of abdominal discomfort or of pain. A slight rise of temperature at times has been noted.

(2) *Ocular type.*—Here the main symptoms are visual in nature. The attack commences with a series of visual experiences of a positive nature (fortification figures, zigzags), or of a negative character (scotomata, hemianopia). These may be accompanied or followed by an illusory distortion of vision, such as the apparent movement or obliquity of objects; diplopia; megalopsia or micropsia; optical alloæsthesia. A state of ocular vertigo follows, often accompanied by pain in the head or in the eyeball. Vomiting usually does not occur. The visual symptoms persist throughout the attack, dominating the picture. Examination usually reveals some slight and uncorrected refractive errors, often heteronymous in type; full correction of these errors often leads to marked relief.

(3) *Menstrual migraine.*—A very common sub-group is occupied by those cases of migraine in females, starting at the time of the first period, and regularly recurring with each succeeding menstruation. The migraine may accompany or closely precede or follow the period. Should the patient miss a period no migraine occurs. During pregnancy the migraine usually ceases, though vomiting may be excessive. At the menopause the migrainous symptoms are aggravated, but they cease with the complete cessation of the climacteric. Whether any structural peculiarities exist in these cases—as, for example, in the region of the sella turcica—is debatable. That special endocrine therapy is indicated in this type of case seems clear from practical as well as theoretical data.

(4) *The "cerebral type."*—A type of migraine in which intense headache, without visual or bilious accompaniments, is the all-important symptom, may perhaps be isolated. Sometimes a focal intracranial lesion is suspected because of the severity of the pain; the dramatic type of onset in some cases; the frequent localisation of the pain to one particular region of the cranium; the severe giddiness, restlessness, irritability, and photophobia suggestive of meningeal irritation. Attacks of this kind may be precipitated by sudden physical exertion, such as running up a station incline carrying a suitcase. Sometimes exposure of the bare head to sunlight ("heat-stroke") may be responsible. The sufferer often has some degree of hyperpiesis with or without arterial change.

An association with cerebral arterial disease is at once suggested, and one naturally asks whether such attacks might not constitute the pre-rupture symptoms of cerebral aneurysm. It is well known that the previous medical history of patients known to suffer from an aneurysm on the circle of Willis may be characterised by periodic "migrainous attacks." The following case is instructive:—

A man of 37 had been subject for 12 years to terrible bitemporal "migrainous" headaches, lasting hours or days. They would occur two or three times a year, and were always precipitated by business or domestic worries. He would disappear into a quiet room and try to sleep off the attack. There would be no vomiting and no visual disorder. In July, 1930, during a typical headache, he collapsed, lost consciousness, and was convulsed down the right side. On regaining consciousness a right hemiparesis with aphasia was found. Lumbar puncture revealed an evenly blood-stained cerebro-spinal fluid. Paretic signs persisted for some weeks.

About five months later the patient reported, according to instructions, at the casualty department, as he was suffering from another of his migraine attacks. Dr. A. Gilpin immediately performed another lumbar puncture and found a cerebro-spinal fluid which contained about 60 red blood-cells per c.mm.

Is it possible to isolate clinically a type of migraine associated with cerebral aneurysm? The inconspicuousness of teichopsia and vomiting is an important point, although visual phenomena have been described in the pre-rupture headaches. Adie believes that the consistency with which a unilateral headache appears on the same side is of importance; in other words, a headache which is left-sided in one attack and right-sided in another argues against the esence of aneurysm. Support is afforded by the monstration of other somatic disorders of developent, such as congenital heart disease, coarctation of e aorta, and skeletal anomalies. Albuminuria ay also be of possible significance.

(5) *Allergic migraine.*—Everyone is familiar with e conception of migraine as an allergic disorder, curring in families in which other allied affections cur. Without question, there are patients in whom igraine occurs in alternation with attacks of asthma, angioneurotic œdema, or of urticaria. Undoubtedly, so, migraine may develop during adolescence after childhood of cyclical vomiting. For these and other asons it appears clear that a type of migraine exists hich bears a close association with disorders of an llergic character. At the same time it must be mphasised that such cases are in the minority, and robably are too few in number to permit far-reaching onclusions as to ætiology or pathogenesis. We feel hat the case for the allergic nature of migraine has een overstated.

MIGRAINE MAJOR

The analogy between migraine and epilepsy has ften been made; the many points of contact between he two disorders serve as useful guides in clinical escription as well as suggestive features in ætiology. ust as we arbitrarily describe a major and a minor orm of epilepsy, so we may isolate a variety of migraine which from its severity and at times almost ramatic characters may be spoken of as "migraine major."

In this category belong the particularly severe xamples of the bilious and of the cerebral types, where the intensity and protraction of the symptoms may arouse doubt as to the original diagnosis. Differentiation will have to be made in such cases rom acute abdominal emergencies and from gross ntracranial disease. The accompanying prostration and loss of weight take these examples of migraine out of the category of a minor malady.

We must mention here those cases where neuro-ogical symptoms are present in striking degree. Thus mental confusion, the paraphasic speech defects, the feelings of numbness in the face or extremities, may be so marked as to suggest cerebral umour or thrombosis. Although these features are not rare even in minor forms, they may occasion difficulty in diagnosis when severe or protracted.

To the group of migraine major also belong certain complicating events of a severe and even alarming nature.

Status hemicranicus.—Occasionally a patient may emerge from a severe bout of migraine only to commence immediately another turn. In this way one attack may succeed another for as long as a month. Upon the analogy of the epileptic phenomenon the term "status hemicranicus" is applied. During this state the patient is never entirely free from headache, though it may fluctuate. Extreme physical and mental prostration may result; the patient may lose a stone or two in weight, and prolonged convalescence may be required. If subjective sensory disturbances occur during each attack, then objective sensory impairment of a hemiplegic distribution may be demonstrable.

This distressing state offers to the researcher an opportunity for clinical and biochemical investigation of the migraine phenomena. The results have been rather meagre, however. From the few facts which have emerged we know that the stomach is dilated, atonic, and immobile. Furthermore, we know—and this will surprise those who envisage in migraine the effects of intracranial hypertension—that the cerebrospinal fluid pressure is reduced, the composition of the fluid being normal. In this way the migraine symptomatology bears a resemblance to the post-lumbar puncture headache.

Migraine-epilepsy must be placed among the major manifestations of the disease. Not only can we trace an analogy between the phenomena in epilepsy and in migraine, but a closer association may at times be traced. Epilepsy may occur among the relatives of a migrainous subject; or epileptic and migrainous attacks may alternate in the same person; or epilepsy may cease and be replaced by attacks of migraine, the fits reappearing in later life when the migraine has abated. The term "migraine-epilepsy" is best restricted, however, to those cases where unconsciousness—with or without convulsions—occurs at the height of the migraine attack. In this way the visual phenomena and the headache act like a slow and prolonged aura. It is noticeable that when a migrainous attack culminates in unconsciousness, the headache is thereby entirely relieved and the attack cut short. Without the unconsciousness the attack would have dragged on for many hours or days, with vomiting and prostration.

The association between epilepsy and migraine is not a simple one. While it is true that epileptic manifestations at times appear in the personal or family history of a migrainous subject, the converse rarely applies. Thus it is distinctly unusual for genuine migraine to occur in subjects who are chronic or confirmed epileptics.

Migrainous neuralgia.—Sometimes the attack of migraine is accompanied and followed for some days by severe neuralgic pain in a limited area of the face or head. The patient may complain of severe pain localised to the eyeballs, the inner canthus, the side of the nose, temple, malar ridge, or mastoid region. Even the neck and shoulders may be affected. The pain may commence in the attack but persist for days or weeks after its finish. No objective sensory disorder can be demonstrated other than local tenderness.

In certain of these cases careful investigation reveals a condition of non-articular rheumatism, as betrayed by a tender nodule or thickening in the muscles or aponeurosis of the head and face. Tenderness along the course of an occipital or supra-orbital nerve may at times be present.

Persistent paralytic manifestations.—These constitute an interesting though uncommon series of phenomena. During the attack of migraine certain neurological signs may appear, and though becoming less noticeable when the attack has ended may not entirely disappear. With succeeding turns they reappear and eventually become permanently installed.

Pupillary inequality may be quoted as an example. The patient's friends may notice that during an attack one pupil becomes much smaller than the other. The difference becomes less noticeable between the attacks. In the course of time the anisocoria becomes permanent, and the patient may present a small inactive pupil on one side, with a normal mid-dilated pupil on the other.

Persistent hemianopia is another well-known sequel of chronic migraine. This defect may appear insiduously as a permanent feature, but more often it is ushered in abruptly at the height of an attack by an epileptiform seizure.

Most characteristic is the well-known ophthalmoplegic migraine, where a recurrent ocular paresis eventually becomes permanent. The third nerve is the one implicated in by far the greatest number of cases, but very exceptionally the fourth or the sixth nerves may be concerned.

Persistent hemiplegia, which may be accompanied by aphasia, has not infrequently been seen after chronic migraine. One patient in our series had suffered for many years from severe recurrent migraine, and later, in middle life, developed with some suddenness paretic manifestations down one side of the body. Similar cases might be quoted from the literature. The well-known Dr. Parry, of Bath, was a lifelong victim of migraine, and indeed wrote one of the classical accounts of this affection. In 1822 he died from the effects of a focal cerebral lesion with hemiplegia, aphasia, and agraphia. The evidence of the pathological data has shown that in these cases the lesions have been thrombotic in type. The coexistence of two such common disorders as migraine and cerebro-vascular disease would not attract attention were it not for the frequent story that the migraine in such cases has been associated with transitory symptoms of speech disturbance, numbness, and weakness affecting one side of the body—symptoms which have been made permanent by the cerebral thrombosis. In such cases one cannot but wonder whether the repeated migrainous attacks may not have so affected the structure of the cerebral blood-vessels as to have facilitated a terminal vascular accident.

MIGRAINE EQUIVALENTS

Pursuing the analogy with epilepsy a little further, we may apply the term "migraine equivalents" to those episodic events which occasionally seem to replace a true attack of migraine. Their nature is varied: they may comprise a period of mental confusion and a sense of unreality lasting for a few hours; a spell of giddiness or of nausea; paroxysmal tachycardia; tinnitus. The transient psychoses are the common equivalents, and naturally alternative diagnoses may be raised. According to J. M. Nielsen, it is necessary for the psychic disturbance to be of short duration (hours to possibly two days); to be unassociated with loss of consciousness; to be non-progressive in character; and not to lead to deterioration. It is highly important that true migraine must also be present, and there must be no evidence of hysterical or of epileptic tendencies. Lastly, the psychical state must be normal between the attacks.

The classic work of E. Liveing contains numerous examples of migraine metamorphoses, as he named these equivalents—including attacks of gastralgia, of angina pectoris, of gout, and of nocturnal laryngeal spasms.

The Migrainous Constitution

Investigation of a case of migraine comprises largely a minute study of the patient's symptoms, the factors of possible predisposing or precipitating significance, the personality of the victim in the widest physical and psychological sense, the record of previous illness, and, finally, the family history.

Physical examination is important, but occupies a secondary place. As in epilepsy, neurological "signs" are usually absent. Errors of refraction and of ocular balance must obviously be sought and corrected. Fundus abnormalities are not typically present; cardiovascular disorders are usually absent. Detailed information as to the physical habitus is lacking on an adequate scale, and herein lies a f for research which might prove of value.

Among the details of personal and family hist which seem of importance we might stress the frequ occurrence of migraine, more especially in a pare than in a collateral; the occurrence at times epilepsy and asthma among the relatives. Th personal study reveals often a young adult of highly strung, intellectual, or artistic temperament. (Th aspect has certainly been overstressed, for w encounter sufferers of all types of intellectual ability in all classes of the community and in all professions Quite often the sufferer is of the "bilious" type—i.e., one easily upset by dietetic excesses in childhood, and most characteristically one who is a poor sailor and readily becomes air-sick or train-sick. Numbers of migrainous sufferers cannot travel in trains, buses, or saloon-cars. Nothing characteristic has yet been determined as regards their appetite and thirst, their fondness or dislike for fats and sugars, &c.

Precipitating factors are extremely variable and individual. In perhaps the majority no clear-cut cause can be assigned to an attack; in some, two or three factors may be suspected; in a few only may a solitary precipitating factor be definitely traceable.

Among the commoner factors should be mentioned the psychological. Without doubt, the factors of suppressed rage and humiliation were operative in determining some of the attacks in certain of our patients. Prolonged stress of a psychogenic character is important, and the victims suffer intensely during a period of mental overwork and anxiety. Dietetic factors are rare, though we have encountered examples where the attacks have been invariably precipitated by a particular foodstuff. Over-eating may be responsible at times. On the other hand, hunger was found to be a commoner and more potent cause. The missing of a meal in the course of a busy day, unwonted exertion "on an empty stomach" are not uncommonly cited as causes of an attack. One person sustained his severest bout after deliberately avoiding food for 24 hours while continuing his usual work. The common early morning occurrence of migraine may perhaps be associated with the long period of gastric inactivity.

Physical over-exertion was blamed in a few of our cases, particularly when associated with hunger. One patient, an international rugger player, never had an attack except after a game of football. Perhaps, however, psychological factors crept in even here, because he tells us that "the attack is particularly severe when I have skippered the team; particularly if we lost the game; and particularly if I felt that the team did not play up as well as they should." The psychologist may well read the factors of "baffled humiliation and rage" between these lines.

Menstruation is, of course, an important precipitating factor, even in those women whose migraine is not of the menstrual type.

Eyestrain may at times be traceable in the immediate ætiology, and the front seats at a cinema, reading in badly lit rooms, or microscopy may occasionally be blamed.

Among the many circumstances which predispose to an attack, though not actually producing one may be mentioned defective ventilation, smoke-laden atmospheres, exacting brain-work, particularly under circumstances of stress or worry, late hours, broken and insufficient sleep, and intercurrent illness.

(*To be concluded*)

TUBERCULOSIS IN CHILDHOOD

ÆTIOLOGY AND PROGNOSIS AS SHOWN BY THE STOMACH LAVAGE METHOD OF OBTAINING TUBERCLE BACILLI *

IN the "Handbuch der Kindertuberkulose" for 30 the present German view of tuberculosis is set rth by Herbert Koch, Epstein, Engel, Priesel, rfl, Liebermeister, Weise, and others, much of the tiology being based upon the well-known researches Ranke.[1] It may be summarised as follows.

After the initial introduction into the body of ubercle bacilli the patient enters the primary tuberulous state, which Ranke has described as characerised by an epithelioid type of tissue reaction naccompanied by allergy—e.g., hypersensitiveness to uberculin. This period varies from two to ten eeks, usually averaging about six weeks. The atient may now recover completely, healing taking lace by rapid calcification without the development f hypersensitiveness to tuberculin, or he may pass nto the secondary state, which is characterised by he rapid development of a high degree of allergy the intradermal tuberculin test showing a positive eaction to 0·1 c.cm. of 1/100 to 1/100,000 tuberculin). n the clinical side this "early" secondary state is ften associated with loss of weight, fever, dry cough, allor, and disturbances of the alimentary tract, hile radiography of the chest may show enlargement f the hilus glands and sometimes "focal" lung eactions. At the same time certain so-called parauberculous conditions, such as erythema nodosum, hlyctenular conjunctivitis, pleurisy, and benign nfiltration of the lung (epituberculosis) are apt to nanifest themselves. This early secondary allergic tate may heal by resorption or may progress, breaking lown the lymphatic gland defences to spread along he lymphatics or by the blood stream, and causing ither metastases or generalised tuberculosis (miliary tuberculosis and caseous broncho-pneumonia). This generalised condition is described as the *late* secondary state.

When recovery from the primary or secondary states occurs, there results a degree of immunity ; if reinfection now takes place, the resulting condition, known as the "third state," differs essentially from the two previous states. The high tissue immunity allows a localisation of infection to take place in the lung tissue ; if the glands become involved (which is less likely) the infection is chronic, and not acute as in the primary state ; fibrosis is a further evidence of high tissue resistance. This third state is adult "phthisis."

The American view, as expressed by Opie,[2] is, in the main, in agreement with that of the German school. It lays stress on the difference in the clinical picture between the tuberculosis of childhood and adult "phthisis," and makes it clear that these differences are due to a varying tissue response on the part of the individual. Opie points out, however, that the types of reaction are not dependent upon age, and that when a primary infection occurs in an adult the reaction is similar to that of the child undergoing a first infection. He considers the primary focus to be situated in the parenchyma, from which infection spreads to the corresponding hilus glands, an idea which is similar to that of the primary lung focus, as described by Ghon.[3] This conception has particular significance in this paper, since the presence of tubercle bacilli in the sputa of children in the primary state suggests a lesion in the lung tissue itself.

OPEN TUBERCULOSIS IN CHILDHOOD

Recently one of us (W. R. F. C.[4]), in a paper on the ætiology of erythema nodosum, showed that this condition follows infection either with the tubercle bacillus or the hæmolytic streptococcus, and is associated with a hypersensitive body reaction to the breakdown products ("endotoxins") of the organism causing the infection. In 3 out of 5 patients with erythema nodosum of the tuberculous type, tubercle bacilli were found in the stomach lavage. The publication of this report, following directly upon the work of Arvid Wallgren [5] and other workers in Europe and America who have called attention to the occurrence of "open" lung lesions in childhood, shed a new light upon the ætiology of tuberculosis in infancy and childhood, which it is the purpose of this paper to discuss. At the same time a number of inquiries have been made about the technical difficulties, value, and practical application of the stomach lavage method of sputum examination in childhood. An attempt will be made to answer these.

The stomach lavage method of detecting tubercle bacilli in sputum has been extensively used since it was first described by Meunier [6] in 1898. Many investigators have published results emphasising the occurrence of positive sputa in varying percentages of children examined. It is now evident that children in the *late secondary state* (generalised lung or miliary tuberculosis) are found more commonly than not to have tubercle bacilli in their sputa. Thus, Armand-Delille [7] claims to be able to demonstrate tubercle bacilli in 100 per cent. of such patients (see special technique in Appendix) ; Drucker [8] also found them in 100 per cent. of 19 infants under 1 year with definite signs of tuberculosis. Poulsen [9] found 100 per cent. of children under 1 year to be positive ; Opitz [10] found them in 8 of 11 children with advanced lung lesions ; Friedlander [11] obtained positive sputa in 7 out of 12 patients with tuberculous meningitis (both by culture and by guinea-pig inoculation) ; Opitz [12] in 7 out of 7 ; and we have found 3 out of 7 children with miliary tuberculosis or meningitis to have positive sputa. On the whole, the younger the child with generalised tuberculosis the easier it is to find tubercle bacilli in the sputum (Poulsen,[9] Delille,[7] Opitz [12]).

We come now to the *early secondary state*. There is evidence to show that this is also, though in a less degree, accompanied by tubercle bacilli in the sputum. Armand-Delille [13] showed that 60 per cent. of 500 children with only radiographical lung shadows to suggest the possibility of tuberculosis had bacilli present in the sputum, and that 3 out of 64 children examined simply as "contacts" were positive. Valdimar Poulsen [9] came to similar conclusions ; Camille Kereszturi [14] and her co-workers in America have demonstrated positive out of

---

* The investigation was undertaken in the Research Department of the Hospital for Sick Children, Great Ormond-street, London, and was assisted by a grant from the Medical Research Council.

40 children with paratuberculous lesions (mainly pleurisy and phlyctenular conjunctivitis); Opitz[12] found 7 positive out of 9 children with "epituberculosis"; Wallgren[5] found tubercle bacilli in 17 out of 37 children with erythema nodosum with positive tuberculin reactions, and Philipson[15] reported the continuance of the above work by Wallgren, showing out of 96 children with erythema nodosum and positive tuberculin reactions 47 had tubercle bacilli in the sputum.

The Present Investigation

The present report consists of an analysis of the results of the stomach lavage in 70 children and infants under the age of 11 years (Table I.). The cases have been divided into five main groups:—

TABLE I

—	Condition.		Total.	Positive lavage (by guinea-pig inoculation).
A	Paratuberculous states		17	5
B	Contact cases..		17	1
C	Miscellaneous cases of suspected tuberculosis	Unresolved pneumonia	4	0
		Bronchiectasis ..	2	0
		Peritonitis ..	1	1
		Intracranial tumour	1	1
		Hæmoptysis (? mitral stenosis)	1	0
		Asthma	2	1
D	Military tuberculosis and meningitis		7	3
E	Control cases		18	0
	Totals		70	12

(*a*) Seventeen children showing *paratuberculous lesions*, such as erythema nodosum, phlyctenular conjunctivitis and pleurisy, together with X ray signs of focal lung reactions or enlarged hilus shadows. Five of the 17 yielded tubercle bacilli, as shown by guinea-pig inoculation. The pigs were killed after six weeks, and it may be that had they been kept longer, or had a double lavage been used (see appendix), more positives might have been obtained.

(*b*) Seventeen *contact cases*. These were children who had been recently exposed to infection from relations with open phthisis, and who gave positive tuberculin reactions but no other evidence of tuberculosis. One of these children was positive—namely, the sister of a child with erythema nodosum, who herself had had a positive stomach lavage. Both children were in contact with a brother who had phthisis (see history in section 2).

(*c*) Eleven *miscellaneous cases* suspected of tuberculosis in the wards of hospital by the physicians in charge. Three of these, a child with an intracranial tumour, a child with asthma, and a child with abdominal tuberculosis were positive.

(*d*) Seven cases of *generalised tuberculosis*. Three of these were positive.

(*e*) Eighteen *control cases*, consisting of children in whom there was no reason to suspect tuberculosis, most being negative to tuberculin. All gave negative results.

In Table II. the positive cases are set out in greater detail. The oldest child is 10 years, and the youngest 3 months; in fact, age seems to play little part in our results. It is interesting to note that the report of the radiologist (made independently) suggests an abnormal condition in every case, but does not always suggest tuberculosis. Our positive results occurred chiefly among children with paratuberculous lesions, as in the American investigation.[14]

Dr. Stanley Griffith, Cambridge, has been kind enough to type the last nine cases for us. Tubercle bacilli in all but one case were found to be human; the one bovine occurred in a child with abdominal tuberculosis.

TABLE II

No.	Disease.	Sex.	Age in Years.	Mantoux.	Guinea-pig result.	Type
1	Erythema nodosum ..	F.	$5^{5}/_{12}$	+	+	—
2	„ „ ..	F.	$3^{4}/_{12}$	+	+	—
3	„ „ ..	F.	7	+	+	—
4	„ „ ..	F.	10	+	+	Human
5	„ „ ..	F.	$2^{9}/_{12}$	+	+	„
6	Intracranial tumour ..	M.	5	+	+	„
7	Asthma	F.	$6^{6}/_{12}$	+	+	„
8	Caseous broncho-pneumonia	F.	$1^{1}/_{12}$	+	+	„
9	Tuberculous meningitis ..	M.	2	+	+	„
10	„ peritonitis ..	M.	$^{3}/_{12}$	+	+	Bovine
11	„ meningitis ..	F.	$^{6}/_{12}$	+	+	Human
12	Contact	F.	$5^{6}/_{12}$	+	+	„

The following two case reports illustrate several important points. Case 1 shows the importance of the recognition of erythema nodosum and other paratuberculous conditions as clinical evidence of primary tuberculosis, and the need in such circumstances of search for the source of infection. Case 2 demonstrates the value in diagnosis of the lavage method in doubtful cases of tuberculosis in childhood.

CASE 1.—Aged 10. Admitted to the Hospital for Sick Children, Great Ormond-street, with erythema nodosum. Family history: no history of contact with tuberculosis could be obtained. Personal history: acute rheumatism during the previous winter. Skin reactions: strongly positive both to tuberculin and hæmolytic streptococcal extract. Radiography: very definite hilus enlargement. In spite of the radiogram, Dr. F. J. Poynton inclined to the diagnosis of a rheumatic or streptococcal origin to the erythema nodosum. The stomach lavage, however, gave a positive sputum, proving the condition to be tuberculous in origin. Subsequently, examination of the brothers and sisters revealed the presence of an elder brother with unsuspected phthisis, with a cavity at one apex and a positive sputum; also in a younger sister, aged 5 years, stomach lavage revealed the presence of tubercle bacilli. In the latter physical signs were absent, radiography was indefinite, and the only symptoms were loss of weight though the Mantoux reaction was strongly positive.

This family demonstrates the importance, first, of the recognition of the significance of the paratuberculous conditions, and then of a thorough search for the source of infection.

CASE 2.—Aged 6. Admitted to the hospital suffering from asthma. She was suspected of being tuberculous because of her poor general condition, a family history of phthisis, and a history of tubercle bacilli being found in her sputum two years previously, on one occasion, at Brompton Hospital. Clinical examination and radiography were uncertain. Mantoux positive. Tubercle bacilli were cultured in the guinea-pig from the stomach washout.

Discussion

THE SIGNIFICANCE OF THE OPEN LESION

The results reported here, together with those of Armand-Delille, Wallgren, Opitz, et al., may be taken as proof of the existence of tubercle bacilli in the sputum of certain children. The percentage frequency with which positive sputa occur in the *primary* and *early secondary* states cannot as yet be exactly gauged. It is possible that most children passing through these states develop, for a short period, an open lesion. Wallgren's[5] observation that tubercle bacilli disappear from the stomach lavage in from two to eight months suggests that the period during which the lesion is open is of such comparatively short duration that it is unlikely to be detected, unless the condition is revealed by paratuberculous lesions. In our investigation all but one of the children with early lesions from whom tubercle bacilli were obtained revealed their condition to us by the coincident occurrence of erythema nodosum or phlyctenular conjunctivitis. The American figures[14] also showed a high incidence among children with paratuberculous lesions—i.e., 30 per cent. in children with, compared with 12 per cent. in children without—while it is significant that Wallgren[5] found 46 per cent. of his children with erythema nodosum to have open lesions. It is, however, quite clear from the results of other workers (Opitz,[12] Armand-Delille,[13] Poulsen[7]) that open lesions occur frequently among children with primary tuberculosis in the absence of paratuberculous lesions. It should not, therefore, be thought that open lesions are necessarily more common in children in whom the primary tuberculous state is associated with paratuberculous lesions, but rather that in these children they are more easily detectable.

The point of origin of these tubercle bacilli cannot be determined with certainty, since these children do not come to autopsy. The work of Ghon,[3] Blacklock,[16] and others, and some of the focal reactions demonstrated by Melville[17] in fine skiagrams suggest, however, that the primary lesion is in the lung parenchyma, and we may hazard the suggestion that the sequence of events is usually as follows: the child inhales tubercle bacilli, which are caught in the parenchyma of the lung; after some six weeks a focal reaction occurs in the lung and later in the glands draining the affected area; at this time tubercle bacilli may be found in the sputum in small numbers; two to four months later healing may take place by resorption, and the open lung lesion close so that tubercle bacilli can no longer be found in the stomach lavage. At present there is little evidence as to the actual frequency of these events. We may, however, quote the words of Armand-Delille, "Il semble que la lésion tuberculeuse est chez l'enfant plus souvent ouverte qu'on ne le pense classiquement."

THE PROGNOSIS OF CHILDREN WITH OPEN LESIONS

The question of prognosis in children who are shown by this method to have open lung lesions has not yet been completely settled. It is interesting to note that Bentley,[18] in an article on tuberculosis, recently stated that it is a "medical curiosity" to find a positive sputum in a child below the age of 10 years, and that when this does occur the prognosis is extremely grave. He was, of course, alluding to the bacilli found in the sputum by ordinary methods, and, as Armand-Delille[13] has shown, tubercle bacilli are only found in this way in gross lung lesions. It is, however, well known that children swallow their sputum, and we wish to make it quite clear that this sputum may contain tubercle bacilli from two different tuberculous conditions, those of the early localised and those of the late generalised secondary states described above. It is evident that many of the children in the late secondary state, where the infection is generalised and the prognosis hopeless, may be found to have tubercle bacilli in their sputum in sufficient numbers for detection by the ordinary method (direct microscopy of expectoration); to this extent we are in agreement with Bentley.

But it is to the existence of the early secondary state, where tubercle bacilli are not found in the sputum by the ordinary method, that we wish to call attention. The prognosis in these children, in our investigation, was good, and in fact no worse than in those in whom it was impossible to demonstrate bacilli. In from 6 to 14 months subsequent to the first positive stomach lavage none of our children have shown general symptoms of the disease, and in a follow-up of some 24 cases of paratuberculosis (erythema nodosum and phlyctenular conjunctivitis) occurring during the last four years at the Hospital for Sick Children, only three were found to have developed any frank tuberculous lesion. Other writers have given varying prognoses; the Norwegian, Engelsgaard,[19] quoted as high a figure as 50 per cent. of the cases developing frank tuberculosis after erythema nodosum; the Americans[14] stated that the children with positive lavage did only slightly less well in the Seaview Sanatorium, New York, than those with negative lavage; Wallgren[5] and Philipson[15] showed that bacilli disappeared from open lesions in Swedish children in from two to six months. It may be said that the prognosis varies with the treatment; all the children from this hospital were carefully supervised, and most of them went away for prolonged convalescence.

In this connexion the work of Borrel[20] on the French African troops in the war is of considerable importance. He showed that these men, who had not previously been exposed, and who came into contact with tuberculosis on arrival in France, reacted to the disease in a similar way to the European child. After the primary infection there was a period of three to four months during which they showed loss of weight, slight fever, alimentary disturbances, increased hilus shadows in the X rays of the chest, and strongly positive tuberculin reactions. At the end of this period they either recovered without further symptoms or the disease became generalised. The prognosis appeared to depend largely upon the treatment afforded during the three months subsequent to the primary infection. If during this period they were taken off heavy duty, given ample diet and rest, the prognosis was extremely good; if, however, they were allowed to continue the full rigours of a soldier's life the disease tended to overcome the body defence and generalise. Fuller investigations are necessary before it will be possible to gain a clearer idea of the prognosis of children with primary tuberculosis showing positive sputa; we may submit, however, that there is reason to suppose it to be good, provided suitable environment, food, fresh air, and rest are secured for them.†

The action to be taken in respect of these children necessarily raises the question of infectivity. There is, at present, no evidence that these children are infective; there is no known instance of one child with erythema nodosum having caused any other child to become infected, and in the school outbreaks of erythema nodosum in Scandinavia recorded by Albin Landau,[21] all the cases were traceable to one older child with open phthisis. It seems unlikely that sputum, which can only be obtained by special technique from the stomach, will ordinarily be a source of infection. There remains the possibility, as Philipson,[15] Valdimar Bie,[22] and Opitz[12] have emphasised, that during fits of violent coughing or sneezing in children with bad colds or coughs,

---

† Since writing the above, Dr. J. W. S. Blacklock's report[16] has been published by the Medical Research Council. This investigation deals with 1800 consecutive post-mortems on children. Of these, 283 showed tuberculous lesions and 173 were considered to be due to primary tuberculous infections of the thoracic tissues; 90 per cent. of those cases which came to autopsy did so directly due to their tuberculous infection. This fact, combined with the comparative rarity of finding similar lesions at adult autopsies, has led Dr. Blacklock to assume that pulmonary tuberculosis is almost always fatal in the west of Scotland. This is a very different finding from our own and others quoted here, and suggests that there is something particularly unfavourably in the environment of Glasgow children acquiring tuberculous infection. It must be remembered, however, that he is approaching the subject purely from the pathological standpoint, and hence his results may not be altogether comparable with ours.

40 children with paratuberculous lesions (mainly pleurisy and phlyctenular conjunctivitis); Opitz[12] found 7 positive out of 9 children with "epituberculosis"; Wallgren[5] found tubercle bacilli in 17 out of 37 children with erythema nodosum with positive tuberculin reactions, and Philipson[15] reported the continuance of the above work by Wallgren, showing out of 96 children with erythema nodosum and positive tuberculin reactions 47 had tubercle bacilli in the sputum.

The Present Investigation

The present report consists of an analysis of the results of the stomach lavage in 70 children and infants under the age of 11 years (Table I.). The cases have been divided into five main groups :—

TABLE I

—	Condition.		Total.	Positive lavage (by guinea-pig inoculation).
A	Paratuberculous states		17	5
B	Contact cases..		17	1
C	Miscellaneous cases of suspected tuberculosis	Unresolved pneumonia	4	0
		Bronchiectasis ..	2	0
		Peritonitis ..	1	1
		Intracranial tumour	1	1
		Hæmoptysis (? mitral stenosis)	1	0
		Asthma	2	1
D	Miliary tuberculosis and meningitis		7	3
E	Control cases		18	0
	Totals		70	12

(a) Seventeen children showing *paratuberculous lesions*, such as erythema nodosum, phlyctenular conjunctivitis and pleurisy, together with X ray signs of focal lung reactions or enlarged hilus shadows. Five of the 17 yielded tubercle bacilli, as shown by guinea-pig inoculation. The pigs were killed after six weeks, and it may be that had they been kept longer, or had a double lavage been used (see appendix), more positives might have been obtained.

(b) Seventeen *contact cases*. These were children who had been recently exposed to infection from relations with open phthisis, and who gave positive tuberculin reactions but no other evidence of tuberculosis. One of these children was positive—namely, the sister of a child with erythema nodosum, who herself had had a positive stomach lavage. Both children were in contact with a brother who had phthisis (see history in section 2).

(c) Eleven *miscellaneous cases* suspected of tuberculosis in the wards of hospital by the physicians in charge. Three of these, a child with an intracranial tumour, a child with asthma, and a child with abdominal tuberculosis were positive.

(d) Seven cases of *generalised tuberculosis*. Three of these were positive.

(e) Eighteen *control cases*, consisting of children in whom there was no reason to suspect tuberculosis, most being negative to tuberculin. All gave negative results.

In Table II. the positive cases are set out in greater detail. The oldest child is 10 years, and the youngest 3 months; in fact, age seems to play little part in our results. It is interesting to note that the report of the radiologist (made independently) suggests an abnormal condition in every case, but does not always suggest tuberculosis. Our positive results occurred chiefly among children with paratuberculous lesions, as in the American investigation.[14]

Dr. Stanley Griffith, Cambridge, has been kind enough to type the last nine cases for us. Tubercle bacilli in all but one case were found to be human; the one bovine occurred in a child with abdominal tuberculosis.

TABLE II

No.	Disease.	Sex.	Age in years.	Mantoux.	Guinea-pig result.	Type.
1	Erythema nodosum ..	F.	$5\frac{5}{12}$	+	+	—
2	„ „ ..	F.	$3\frac{4}{12}$	+	+	—
3	„ „ ..	F.	7	+	+	—
4	„ „ ..	F.	10	+	+	Human.
5	„ „ ..	F.	$2\frac{9}{12}$	+	+	„
6	Intracranial tumour ..	M.	5	+	+	„
7	Asthma	F.	$6\frac{6}{12}$	+	+	„
8	Caseous broncho-pneumonia	F.	$1\frac{1}{12}$	+	+	„
9	Tuberculous meningitis ..	M.	2	+	+	„
10	„ peritonitis ..	M.	$\frac{3}{12}$	+	+	Bovine
11	„ meningitis ..	F.	$\frac{6}{12}$	+	+	Human.
12	Contact	F.	$5\frac{6}{12}$	+	+	„

The following two case reports illustrate several important points. Case 1 shows the importance of the recognition of erythema nodosum and other paratuberculous conditions as clinical evidence of primary tuberculosis, and the need in such circumstances of search for the source of infection. Case 2 demonstrates the value in diagnosis of the lavage method in doubtful cases of tuberculosis in childhood.

CASE 1.—Aged 10. Admitted to the Hospital for Sick Children, Great Ormond-street, with erythema nodosum. Family history: no history of contact with tuberculosis could be obtained. Personal history: acute rheumatism during the previous winter. Skin reactions: strongly positive both to tuberculin and hæmolytic streptococcal extract. Radiography: very definite hilus enlargement. In spite of the radiogram, Dr. F. J. Poynton inclined to the diagnosis of a rheumatic or streptococcal origin to the erythema nodosum. The stomach lavage, however, gave a positive sputum, proving the condition to be tuberculous in origin. Subsequently, examination of the brothers and sisters revealed the presence of an elder brother with unsuspected phthisis, with a cavity at one apex and a positive sputum; also in a younger sister, aged 5 years, stomach lavage revealed the presence of tubercle bacilli. In the latter physical signs were absent, radiography was indefinite, and the only symptoms were loss of weight though the Mantoux reaction was strongly positive.

This family demonstrates the importance, first, of the recognition of the significance of the paratuberculous conditions, and then of a thorough search for the source of infection.

CASE 2.—Aged 6. Admitted to the hospital suffering from asthma. She was suspected of being tuberculous because of her poor general condition, a family history of phthisis, and a history of tubercle bacilli being found in her sputum two years previously, on one occasion, at Brompton Hospital. Clinical examination and radiography were uncertain. Mantoux positive. Tubercle bacilli were cultured in the guinea-pig from the stomach washout.

Discussion

THE SIGNIFICANCE OF THE OPEN LESION

The results reported here, together with those of Armand-Delille, *Wallgren*, *Opitz*, *et al.*, *may* be taken as proof of the existence of tubercle bacilli in the sputum of certain children. The percentage frequency with which positive sputa occur in the *primary* and *early secondary* states cannot as yet be exactly gauged. It is possible that most children passing through these states develop, for a short period, an open lesion. Wallgren's[5] observation that tubercle bacilli disappear from the stomach lavage in from *two to eight months suggests* that the period during which the lesion is open is of such comparatively short duration that it is unlikely to be detected, unless the condition is revealed by paratuberculous lesions. In our investigation all but one of the children with early lesions from whom tubercle bacilli were obtained revealed their condition o us by the coincident occurrence of erythema nodosum r phlyctenular conjunctivitis. The American figures[14] lso showed a high incidence among children with aratuberculous lesions—i.e., 30 per cent. in children ith, compared with 12 per cent. in children without—hile it is significant that Wallgren[5] found 46 per ent. of his children with erythema nodosum to have pen lesions. It is, however, quite clear from the esults of other workers (Opitz,[12] Armand-Delille,[13] oulsen[7]) that open lesions occur frequently among hildren with primary tuberculosis in the absence of aratuberculous lesions. It should not, therefore, e thought that open lesions are necessarily more ommon in children in whom the primary tuberculous state is associated with paratuberculous lesions, but ather that in these children they are more easily detectable.

The point of origin of these tubercle bacilli cannot be determined with certainty, since these children do not come to autopsy. The work of Ghon,[2] Blacklock,[16] and others, and some of the focal reactions demonstrated by Melville[17] in fine skiagrams suggest, however, that the primary lesion is in the lung parenchyma, and we may hazard the suggestion that the sequence of events is usually as follows: the child inhales tubercle bacilli, which are caught in the parenchyma of the lung; after some six weeks a focal reaction occurs in the lung and later in the glands draining the affected area: at this time tubercle bacilli may be found in the sputum in small numbers; two to four months later healing may take place by resorption, and the open lung lesion close so that tubercle bacilli can no longer be found in the stomach lavage. At present there is little evidence as to the actual frequency of these events. We may, however, quote the words of Armand-Delille. "Il semble que la lésion tuberculeuse est chez l'enfant plus souvent ouverte qu'on ne le pense classiquement."

THE PROGNOSIS OF CHILDREN WITH OPEN LESIONS

The question of prognosis in children who are shown by this method to have open lung lesions has not yet been completely settled. It is interesting to note that Bentley,[18] in an article on tuberculosis, recently stated that it is a "medical curiosity" to find a positive sputum in a child below the age of 10 years, and that when this does occur the prognosis is extremely grave. He was, of course, alluding to the bacilli found in the sputum by ordinary methods, and, as Armand-Delille[13] has shown, tubercle bacilli are only found in this way in gross lung lesions. It is, however, well known that children swallow their sputum, and we wish to make it quite clear that this sputum may contain tubercle bacilli from two different tuberculous conditions, those of the early localised and those of the late generalised secondary states described above. It is evident that many of the children in the late secondary state, where the infection is generalised and the prognosis hopeless, may be found to have tubercle bacilli in their sputum in sufficient numbers for detection by the ordinary method (direct microscopy of expectoration); to this extent we are in agreement with Bentley.

But it is to the existence of the early secondary state, where tubercle bacilli are not found in the sputum by the ordinary method, that we wish to call attention. The prognosis in these children, in our investigation, was good, and in fact no worse than in those in whom it was impossible to demonstrate bacilli. In from 6 to 14 months subsequent to the first positive stomach lavage none of our children have shown general symptoms of the disease, and in a follow-up of some 24 cases of paratuberculosis (erythema nodosum and phlyctenular conjunctivitis) occurring during the last four years at the Hospital for Sick Children, only three were found to have developed any frank tuberculous lesion. Other writers have given varying prognoses; the Norwegian, Engelsgaard,[19] quoted as high a figure as 50 per cent. of the cases developing frank tuberculosis after erythema nodosum; the Americans[14] stated that the children with positive lavage did only slightly less well in the Seaview Sanatorium, New York, than those with negative lavage; Wallgren[5] and Philipson[15] showed that bacilli disappeared from open lesions in Swedish children in from two to six months. It may be said that the prognosis varies with the treatment; all the children from this hospital were carefully supervised, and most of them went away for prolonged convalescence.

In this connexion the work of Borrel[20] on the French African troops in the war is of considerable importance. He showed that these men, who had not previously been exposed, and who came into contact with tuberculosis on arrival in France, reacted to the disease in a similar way to the European child. After the primary infection there was a period of three to four months during which they showed loss of weight, slight fever, alimentary disturbances, increased hilus shadows in the X rays of the chest, and strongly positive tuberculin reactions. At the end of this period they either recovered without further symptoms or the disease became generalised. The prognosis appeared to depend largely upon the treatment afforded during the three months subsequent to the primary infection. If during this period they were taken off heavy duty, given ample diet and rest, the prognosis was extremely good; if, however, they were allowed to continue the full rigours of a soldier's life the disease tended to overcome the body defence and generalise. Fuller investigations are necessary before it will be possible to gain a clearer idea of the prognosis of children with primary tuberculosis showing positive sputa; we may submit, however, that there is reason to suppose it to be good, provided suitable environment, food, fresh air, and rest are secured for them.†

The action to be taken in respect of these children necessarily raises the question of infectivity. There is, at present, no evidence that these children are infective; there is no known instance of one child with erythema nodosum having caused any other child to become infected, and in the school outbreaks of erythema nodosum in Scandinavia recorded by Albin Landau,[21] all the cases were traceable to one older child with open phthisis. It seems unlikely that sputum, which can only be obtained by special technique from the stomach, will ordinarily be a source of infection. There remains the possibility, as Philipson,[15] Valdimar Bie,[22] and Opitz[12] have emphasised, that during fits of violent coughing or sneezing in children with bad colds or coughs, particularly whooping-cough, the bacilli may be expectorated. The elucidation of this point requires further study. At present we feel that these children should be treated as non-infective, and probably the ideal place for them to enter after prolonged convalescence is (in those above 3 years of age) the open-air school.

---

† Since writing the above, Dr. J. W. S. Blacklock's report[16] has been published by the Medical Research Council. This investigation deals with 1800 consecutive post-mortems on children. Of these, 283 showed tuberculous lesions and 173 were considered to be due to primary tuberculous infections of the thoracic tissues; 90 per cent. of those cases which came to autopsy did so directly due to their tuberculous infection. This fact, combined with the comparative rarity of finding similar lesions at adult autopsies, has led Dr. Blacklock to assume that pulmonary tuberculosis is almost always fatal in the west of Scotland. This is a very different finding from our own and others quoted here, and suggests that there is something particularly unfavourably in the environment of Glasgow children acquiring tuberculous infection. It must be remembered, however, that he is approaching the subject purely from the pathological standpoint, and hence his results may not be altogether comparable with ours.

CONCLUSION

In conclusion, we submit that the recognition of the primary state, with its open lesion capable under correct treatment of early healing, is of the very greatest importance. We should like to emphasise the necessity for regarding all children with erythema nodosum, phlyctenular conjunctivitis, pleurisy, or benign infiltration of the lung (epituberculosis) as probably having open lung lesions. In the absence of any paratuberculous lesion, the diagnosis of the primary state remains very difficult, and can only be made by combining radiographical examination, skin reactions, a consideration of the general clinical condition, and the history of contact with open phthisis.

Appendix

INVESTIGATIONS BY PREVIOUS WORKERS

The following is a brief summary of reports already mentioned.

1. *Armand-Delille,*[7] of Paris, in 1927, examined directly homogenised stomach lavage—i.e., not cultured in the guinea-pig—and found 34 positives in 110 children suspected of tuberculosis. He divided his cases as follows : (*a*) Thirteen children with obvious clinical and radiographical evidence of tuberculosis—all positive. (*b*) Thirty-three children with only radiographic evidence—18 positive. (*c*) Sixty-four children examined as contacts—3 positive. (No ages given, no mention of paratuberculous lesions, no details of cases.) In 1930 he published[13] the results of the three following years' work. He says that in 500 cases the tubercle bacillus could be demonstrated in 100 per cent. of children with physical and radiographical signs of caseous bronchopneumonia, and in 60 per cent. of children with radiographical shadows suggesting tuberculosis. (No ages given, no mention of paratuberculous lesions, no details of cases.)

2. *Poulsen,*[9] of Copenhagen, in 1931, was able to demonstrate tubercle bacilli from stomach lavage injected into the guinea-pig in 53 out of 110 children. These children he arranged into age-groups, with the result that of 62 children below the age of 3, 41 were found to have open lesions, while of 48 over the age of 3, only 12 were positive. Poulsen is careful to explain that in Copenhagen all children under the age of 3 suspected of tuberculosis are sent to the children's hospitals, while those over 3 go to special tuberculosis wards ; in this way he accounts for the discrepancy in age results. Poulsen found that in the cases of 19 infants below the age of 1, 100 per cent. had tubercle bacilli in the sputum. He cites cases in which a definite diagnosis could only be made by this method. (No mention of paratuberculous lesions.)

3. *Drucker,*[8] of Copenhagen, in 1930, showed that in 19 children under 1 year of age who had a positive tuberculin skin reaction and radiographic shadows in the lungs, all had virulent tubercle bacilli in the sputum, obtained by stomach lavage.

4. *Wallgren,*[6] in 1931, demonstrated tubercle bacilli by stomach lavage and guinea-pig inoculation in 17 children with erythema nodosum out of 37 who had positive Mantoux reactions. He made the important observation that the sputa became negative, as shown by repeated examinations, in two to eight months.

5. *Philipson,*[15] in 1932, reported on the continuance of the above work by Wallgren after 100 children with erythema nodosum had been examined in this way. His results showed that of 96 who had positive Mantoux reactions, 47 were found to have tubercle bacilli in the sputum. His results have been graded into three groups depending on the increase of hilus shadows, with the result that group 1, with the smallest shadows, had 27 positive per cent. ; group 2, 43 ; and group 3, with the largest hilus shadows, 73 per cent. He also showed that the average length of time that the lesions remained open was two to six months.

6. *Opitz,*[10] in 1928, demonstrated the superiority of guinea-pig culture of stomach lavage material, and other fluids over direct microscopy or culture on Petroff's medium. In 33 sputa, 25 per cent. were positive by direct microscopy, 50 per cent. by Petroff culture, and 66 per cent. by guinea-pig culture. In 11 cerebro-spinal fluids from tuberculous meningitis, 60 per cent. were positive by direct microscopy, 64 per cent. by Petroff, and 100 per cent. by guinea-pig culture. In 6 pleural or peritoneal fluids none was positive by direct microscopy, or by Petroff, and 5 by guinea-pig culture.

Opitz,[12] in 1930, demonstrated tubercle bacilli in the stomach lavage by guinea-pig culture in 28 out of 30 cases of benign infiltration (epituberculosis) of the lung, in 1 out of 7 children with "interlobar pleurisy," in 3 out of 24 with "hilus tuberculosis," in 7 out of 7 with tuberculous meningitis, in 2 out of 6 with tuberculous knees, and in 1 out of 3 with enlarged cervical glands. In his children with epituberculosis he demonstrated bacilli at intervals of a few months for varying periods up to 2 years. Out of 42 positive results he only obtained 2 above the age of 4 years. Opitz considers the question of the infectivity of these children, and says that they may be infective during periods of severe cold or cough; he considers, however, that it would be a great mistake to expose them to superinfection by isolation with cases of phthisis.

7. *Keresztúri*[14] et al, in America, in 1932, examined 40 children in this way, all of whom were suspected of tuberculosis, and the majority having radiographic changes in the lungs. Seven of the 40 had tubercle bacilli in the sputum from stomach lavage, as follows : 2 in pleurisy with effusion ; 1 in pleurisy and phlyctenular conjunctivitis ; 2 in interlobar pleurisy with infiltration ; 1 in central infiltration ; 1 in spondylitis.

They point out that most of their positive cases had some paratuberculous lesion, though this in the case of interlobar pleurisy and central infiltration was only diagnosable by X rays. It was significant that 3 children with paratuberculous lesions, diagnosable without the use of X rays, gave positive results out of 10 such children, and that only 1 positive was obtained from a child who had no paratuberculous lesion whatever out of 30 such children. The average age of positive results was given as 4·4 years.

8. *Friedlander,*[11] in 1930, in Germany, examined the gastric lavage of 12 children with tuberculous meningitis. The sputum was grown on Petroff's medium, and also cultured in the guinea-pig. In 7 out of the 12 tubercle bacilli were found.

9. Bie,[22] in a small investigation on 12 children, Pirquet-positive, found 4 to yield tubercle bacilli in the stomach lavage grown on Petroff, and injected into the guinea-pig. All 4 of the children were below the age of 5 years. A number of Pirquet-negative children were all found to have negative stomach lavage.

TECHNIQUE OF THE STOMACH LAVAGE

This method, first described by Meunier in 1898, consists in making the child cough first thing in the morning, before any food has been taken, and then washing the stomach out with 200 c.cm. of normal saline. The centrifuged deposit is then injected into the guinea-pig, and the animal later killed for evidence of tuberculosis.

We have somewhat modified this technique, and now use the following :—

1. Two grains of potassium iodide are given three times a day for two days before the lavage.
2. The child is encouraged to cough first thing in the morning for 20 minutes.
3. He is then given 100 c.cm. of boiled water to drink.
4. Fifteen minutes later a stomach-tube is passed and as much fluid as possible withdrawn from the stomach.
5. This fluid is centrifuged and the deposit is treated with 1/10 antiformin (4 c.cm. diluted antiform being added to 100 c.cm. lavage).

More recently we have used a method suggested by Dr. S. Griffith, which consists in adding a 10 per cent. potassium hydroxide solution to the stomach lavage to make a final dilution of 1 per cent. This is allowed to act for an hour and then the whole is centrifuged. This method has the advantage of ensuring that the tubercle bacilli are not destroyed, but has the drawback that it leaves the deposit too thick for direct examination.

6. It is then injected under the skin in the abdominal region of the guinea-pig.
7. The guinea-pig is watched for six weeks, after which it is killed and examined for tuberculosis, both by direct smear of the diseased glands and by culture.

Dr. Stanley Griffiths thinks that guinea-pigs which do not show clinical evidence of tuberculosis should be left at least three months; if they die or are killed within six to eight weeks, cultures should be sown from the glands adjacent to the seat of inoculation, even when no lesions are visible. Opitz [10] says that when there were certain signs of tuberculosis he killed the pigs in five to six weeks, and that otherwise he left them for three months, and he also says [12] that he found it useful to test his guinea-pigs with tuberculin; those yielding positive skin reactions were killed at once—i.e., at the most after four to six weeks. Those negative he kept for three months before killing. We were only able to keep our guinea-pigs for six weeks, and it is possible that we may have missed a few positives. It is also of interest that Philipson has shown that by using the material from lavage on two successive mornings he was able to increase slightly the number of his positives.

The above method is comparatively simple, but requires the coöperation of a ward sister used to the handling of children. Herein lies a somewhat variable factor.

Armand-Delille has suggested a different technique which allows an immediate diagnosis if the finding of acid-fast bacilli is considered sufficient proof that the organisms are tubercle bacilli. The sputum contains so few organisms that a method of reducing the size of the centrifuged deposit by getting rid of as much of the mucus as possible is necessary before the bacilli can be seen in the direct smear. This he does by homogenisation as follows:—

1. Centrifuge the lavage in four tubes.
2. Place precipitates in porcelain dish containing 50 c.cm. of water.
3. Add 10 drops of normal sodium hydroxide solution.
4. Heat for ten minutes while slowly adding 50 c.cm. of water.
5. If specific gravity is over 1004 add a little alcohol.
6. Centrifuge liquid again for 45 minutes.
7. Stain by Ziehl Neelsen and examine for tubercle bacilli.

THE VALUE OF STOMACH LAVAGE

Little difficulty has been experienced in obtaining sputum by this method from every child. The majority of children appear to be excreting some small quantity of sputum, and this is normally swallowed. The technique of culture in the guinea-pig presents no great difficulty to the pathologist. Unfortunately at present the culture requires at least six weeks, and this, in many instances, robs the result of clinical value. Recently, however. Armand-Delille [13] has demonstrated tubercle bacilli in direct smears of the sputum obtained by stomach lavage using a different technique, while Ninni [25] is claiming that the injection direct into a cervical gland allows the diagnosis to be made in a week. In this present investigation we made use only of the method of guinea-pig inoculation.

The value of the test is very largely in its definiteness: a positive result means definite tuberculosis. All other methods of diagnosis—e.g., clinical examination, radiography, tuberculin reactions, &c.—however they may incline us to suspect a tuberculous condition of the lungs, fail to supply absolute proof. Delille [13] is emphatic on this point, and says:—

> "On ne saurait affirmer, en effet, qu'un enfant n'a pas de lésion pulmonaire tuberculeuse si on n'a pas fait cet examen; nous considérons même qu'on lui devrait accorder autant d'importance qu'à la radiographie."

We think, also, that the very great delicacy of the test should be emphasised. Armand-Delille [13] was able to show that direct examination of sputum obtained by tickling the back of a child's throat, did little more than demonstrate tubercle bacilli in cases of gross lung lesion—e.g., caseous broncho-pneumonia. His figures for direct examination of material from stomach lavage showed a greatly increased range of positive results; his final method of homogenisation again increased this range, so that it was now evident that the presence of even a few bacilli was being detected. From the work of Wallgren [5] and Opitz [12] it would appear that guinea-pig culture is a test of even greater delicacy, and it is certain that this last method, which we have adopted, may reveal the presence of bacilli in extremely small numbers. The superiority of guinea-pig culture over direct microscopy or growth on Petroff's medium is evidenced by the figures of Opitz [10]: in 33 cases of suspected lung tuberculosis 25 per cent. were positive by direct microscopy, 50 per cent. by growth on Petroff's medium, and 66 per cent. by guinea-pig culture. Opitz says:—

> "Wir sehen also dass das Kulturverfahren noch dann zum Nachweis von Tuberkelbazillen furhen kann wenn die mikroskopische Untersuchung in Stich lasst."

So far as we have been able to judge, the test is reliable; a positive result would seem to be proof of tuberculosis, as in no instance did a control case yield a positive result, and such autopsies as were obtainable in children who died in the secondary state revealed a primary focus in the lung parenchyma.

A negative result does not mean that tuberculosis is absent unless the lavage has been repeated several times, since the practical difficulties in obtaining the sputum by this method allow a considerable margin of error.

We may, therefore, say of the method that its definiteness, together with its delicacy and reliability, justify its use in any case of suspected lung tuberculosis in which a diagnosis is required.

We wish to express our gratitude to Dr. Stanley Griffith for his help and encouragement throughout this work. Our sincere thanks are due to the staff of the Hospital for Sick Children, Great Ormond-street, for allowing us to use and publish the cases here quoted. We also wish to thank Prof. T. W. T. Dillon for his help and advice with some of the foreign literature, and Mr. J. A. Swan for his technical assistance.

HIGH BLOOD PRESSURE

THE PROBLEM OF ITS CONTROL

By C. B. Rossiter, M.D. Durh., F.R.C.S. Edin.
FORMERLY HON. PHYSICIAN, AUCKLAND HOSPITAL, NEW ZEALAND

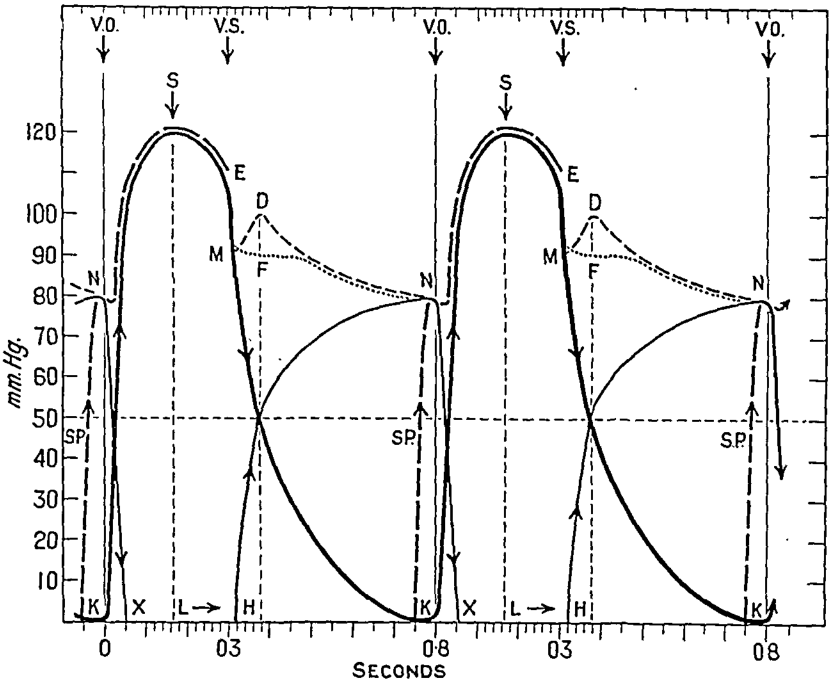
When, with the aid of a sphygmomanometer, the practitioner has come to the conclusion that his patient is "suffering from high blood pressure," at least three questions require answering: (1) Which factor or factors among those which are responsible for normal pressure are at fault? (2) Is it possible to control the erring factor? (3) Is control justifiable?

I venture to state that, owing to the chaotic character of present-day teaching, the solution of any one of these problems presents the greatest difficulty. Many prominent clinicians have suggested that high pressure may be of a compensatory character, and as such should not be unduly interfered with, although no definite theory has been advanced in support of their views. The attitude of many practitioners towards sphygmomanometry recalls that adopted to thermometry in my early days when, if pyrexia was discovered, it had to be reduced at all costs by so-called antipyretics. Fever is now viewed as an index of the combat proceeding between the natural protective powers of the body and the noxious agent and as beneficial in itself. I shall endeavour to give definite reasons why the time has arrived when hyperpiesis should be, at least to some extent, regarded analogously.

The paper represents an attempt to show the practical utility of the theory of an arterial systole which I set forth in a recent number of this journal,[1] and I am herein assuming that such a systole exists.

The complicated nature of the interaction between the various factors which promote blood pressure may be roughly illustrated as follows. During ventricular systole the factors concerned are: (1) rate; (2) volume; (3) force; (4) general arterial volume; (5) elasticity of arteries; (6) sectional area of arteriolar-capillary junction, and the "hydraulic head" representing the resistance of the capillaries and veins beyond; (7) frictional condition and extent of arterial endothelial surface; (8) viscosity of blood. During diastole, ventricular force is replaced by the "arterial systole" assisted by the elastic recoil which takes the place of the elastic resistance, these constituting the driving force. There are, therefore, eight factors during either phase, each of which may have at any time a plus, minus, or normal value. The combinations possible through the interaction of these values amount to many thousands and suggests a problem in higher mathematics, but fortunately I am dealing principally only with the effect which the modification of one factor has upon arterial pressure.

Fig. 1



Graph depicting two successive normal heart cycles (0·8 sec.). The upper composite line, NSEMDN, corresponds to normal intra-arterial pressure.
Thick interrupted line, SPNSE = ventricular systolic pressure, reaching maximum at S and ending E. Portion SP = presphygmic rise, which does not affect intra-arterial pressure, merely serving to force valves open at N. V.O. = opening of valves. V.S. = closing of valves.
Thick continuous line = elastic pressure due to varying volume of blood. Portion K (zero) to E = while ventricle is acting. E to M = immediately after valves close. M down to K = curve resulting from added arterial muscular compression, accelerating evacuation.
Fine dotted line, MFN = course which would be taken by thick line if no muscular compression was acting.
Thin continuous line = pressure on arterial contents due to muscular coat, starting at H (zero) after latent period L→H, rising to N, where it serves to hold valves closed while SP is rising. Then dropping sharply to X (zero).
Thin interrupted line, MDN = resultant pressure curve of added muscular and elastic effects. D = dicrotic wave. M = incisura.
Note that the vertical line dropped from D intersects elastic curve at 50 mm. Hg, and the muscular at 50 mm. Hg, the total forces acting on arterial contents at this moment being 100 mm. Hg.

Fig. 1 (reproduced from my former paper) illustrates how these factors coöperate. The "general volume" is for practical purposes taken as zero or the base line. The elastic tension depends on the contained volume, so the space between the line KSMK and the base may represent the "excess" volume at any moment. As the total systolic volume would not be evacuated without the assistance of HN in 8/10 sec. (according to my hypothesis) this could be represented by prolonging the line KSMFN to the right until it cuts the base line at the expiration of the time which a simple unaided elastic artery would take to dispose of all the added volume. The space between this line and the base might then be regarded as the total excess volume injected during systole. Its insertion would make the diagram too complicated. The "resistance" which comprises the three factors 6, 7, 8 will determine the position of the point N on V.S., so N may be taken as its index for practical purposes. It is obvious that any one of the three can therefore affect the pressure.

PECULIAR PROPERTIES OF ARTERIES

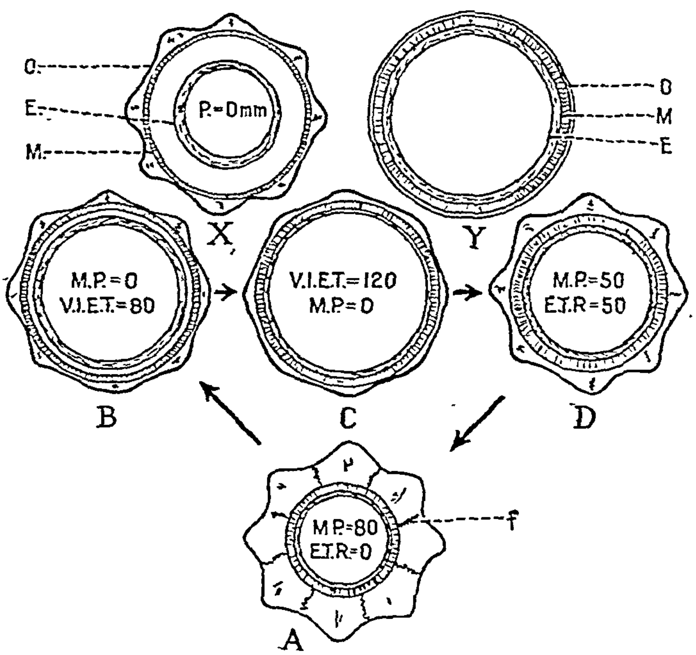
An artery may be considered to be made up of three tubes ensheathing each other—viz., inner elastic, middle muscular, and outer fibrous. Each tube has its own distinct physical part in the hydrodynamics of the circulation. Fig. 2 represents transverse sections of these "tubes" in their different stages of activity during the cardiac cycle. Figs. 1 and 2 are complementary to one another, and should be compared as my argument proceeds, especially as some of these stages do not follow the conventional lines but those of my former paper.

An elastic tube has its smallest diameter when fully relaxed. The amount of force available on recoil is practically equal to that required to distend it to any given diameter, and therefore depends on its contained volume at any time and the "quality" of its elasticity; otherwise it is inert. A muscular (involuntary) tube has its smallest diameter when fully contracted and its largest when relaxed, unless stretched. It is peculiar that if such a tube, when contracted, be forcibly dilated, it will suddenly relax. But if slowly stretched it will relax pari passu with the stretching force, or may even resist it. If it be *suddenly forcibly* stretched it will violently contract. Thus while an elastic tube will be always exerting pressure on its contents when above its normal diameter, a muscular one may be either compressing its contents or be completely relaxed, and have the same diameter in both cases. When contracting over an elastic tube its force will be added to the elastic tension (if any), but if the contraction pressure relaxes step by step, with increasing distension of the inner tube, it may offer no resistance nor add to the distensile force necessary, as would be the case if it were made of elastic material.

Fig. 2, X represents an artery with all its coats relaxed and its contained blood at zero pressure. The outer sheath is shown as an undulating line to indicate "slackness." Actually, of course, this puckering takes the form of transverse, not longitudinal ridges. Y is a vessel dilated to its maximum, which probably never occurs, as it would then function as a rigid tube, the outer coat being taut and acting like the network of cord which surrounds the second bulb of a perfume spray to prevent it from bursting. A is the state of affairs (shown in Fig. 1 at N) when the valves are about to open at the end of diastole. The inner tube is fully relaxed, as at X, and exerts no pressure, while the middle one is firmly contracted round it with a pressure of, say, 80 mm. Hg (Fig. 1, N on line HN). The next stage is B, immediately after the valves have opened, the middle coat relaxing, and the inner distended by ventricular systole up to 80 mm. (Fig. 1, between K and N). From now pressure rapidly rises to its maximum at C. The middle is stretched preparatory to the onset of its succeeding contraction. The elastic tension is, say, 120 mm., and the muscular pressure nil (Fig. 1, S). In D the middle is contracting on the inner, both pressures being equal and totalling 100. This is shown on Fig. 1 as the moment of the summit of the dicrotic wave D. The middle coat from now onwards helps to squeeze forward the blood, assisted by the elastic tension, until the position at A is reached once more; arterial volume is zero, and the inner coat is relaxed, so far as its elasticity is concerned.

There is also a peculiarity about the tissue intervening between the coats or "tubes." That between the inner and middle is areolar and non-elastic, whereas elastic fibrils are present between the outer and middle, running more or less horizontally across (A f). The only function I can assign to the fibrils is to assist the muscular coat to relax, as they would be useless otherwise unless concentrically arranged, like the inner coat. When the tunica media is contracted, they would be extended, as one end of the fibril is anchored to the external tough fibrous coat which in its turn is attached to the tissues contiguous to the artery. The other end is fixed to the periphery of the middle coat. On relaxation of the muscle, therefore, the recoil of the fibres would pull the circumference of the muscular coat outwards, assisting in its rapid relaxation, for instance when urgently required between stages A and B. This seems to be another point in favour of my views on an arterial systole.

FIG. 2



E.T.R.= elastic tension recoil. M.P.= muscular pressure. V.I.E.T.= E.T. due to ventricular injection. O., M., and E.= the three arterial coats (outer muscular, and elastic).

The general clinical conception of high pressure is that it necessarily depends solely on the amount of distension set up in the arterial walls and the quality of the elasticity, whereas, if the state of affairs represented at Fig. 1, N, or Fig. 2, A, is considered, this cannot be correct. During the whole of diastole, pressure may be due partly to muscular compression and partly elastic. Hence, if diastolic pressure be hyper-normal, both these factors must be taken into consideration. If diastolic pressure be raised, systolic must follow suit, and the muscular factor becomes one of great importance. For instance, suppose that an artery is over-distended during diastole to a pressure of 200 mm. Hg, and is in danger of rupture, it is an obvious advantage for its inner coat to be embraced by a muscular one capable of rhythmically contracting with a force, say, of 50 mm., which would thus reduce the strain upon the inner by this amount, and assist in the propulsion onward of its blood. But the effect of this would be to raise the intravascular pressure momentarily to 250 mm.; in other words, a clinical diastolic pressure of 250 mm. due to the combined effect is quite a different affair to one of 250 mm. arising from distension alone. Therefore, if a vago-depressant drug were to be given in the former case, it would aggravate the condition by handicapping the muscle. This can also be illustrated by lowering the curve HN on the graph, which would result in MK falling more gradually, so as to cut the vertical V.S. above zero, so entailing more ventricular force at the succeeding cycle in order to overcome the now distended artery, if the same volume is to be injected. In other words, pressure must rise.

I presume that I have made it clear that this muscular contraction has nothing in common with that very vague state of affairs denoted "spasm of the peripheral arterioles" which, text-books aver, sets up high pressure. Patients suffering from hyperpiesis may be divided into two classes. In one there is evidence of organic pathological change in the vascular tissues; in the other nothing can be found, at least with any means at present at the disposal of a practitioner. This latter group includes that which has, in accordance with the best professional traditions, been christened "essential hypertonia." I do not propose to enter into details regarding the structural changes brought about by disease, being here mainly concerned with the mechanical effect of such changes. Moreover, Prof. Plesch [3] has quite recently provided the readers of this journal with an excellent and comprehensive review of this aspect of arterio-sclerosis, in which, I am comforted to note, he comes to the conclusions regarding treatment which I arrived at years ago, when they were considered rank heresy. Suffice it to state that, in arterial disease, the physical or hydro*dynamic function of each coat is impaired in proportion* to its progress. Impairment of the musculosa implies a gradual lowering of HN, with a corresponding rise in MK, and as a result the general "distensile" pressure rises. What possible benefit can result from the administration of a "vago-depressant" or muscular paralysant under such circumstances? On the other hand, giving a vascular stimulant is like whipping a dying horse. In my experience, from the point of view both of effectiveness and of the patient's comfort, vago-depressants are worse than useless, at the most bringing about a temporary fall due to a general increase in the capacity of the circulatory "viscus."

ESSENTIAL HYPERTONIA

In essential hypertonia the conditions are somewhat different. Here I should feel inclined to name viscosity as the erring factor. One of the commonest cases of this type met with in general practice is climacteric hyperpiesis. I do not know whether systematic investigation has been made of the viscosity in these cases; if not, it might prove instructive. Where the red count is high, pressure often, if not always, follows suit; why not also the white? or both? While viscosity depends on the serum as well as the corpuscles, the former varies but slightly compared with the latter. It is significant that the normal variation of cat's blood, which has a viscosity three times that of water, may be 2·2 to 4 times.[4] Such variations may account for the familiar changes in the normal pressure readings during the day. Friction being inversely proportional to the velocity, and the rate of flow directly proportional to the driving power, it follows that, with increased velocity, greater driving force during diastole or systole will be required to overcome the resistance. At the "climacteric," muscular excitability is well known, hence the arterial muscular response to the stretching stimulus may be increased. *Consideration of the graph will show that increased* HN against increased resistance can reduce the arterial calibre to zero if HN be sufficiently high. Even if the latter remain only at its normal value, it will be of much service in controlling the distensile pressure which would in such a case certainly tend to rise. In both cases internal pressure at N would therefore be above normal (taken as 80 mm.). Thus in two cases, each with a clinical pressure of, say, 120 mm. at N, in that due to tunica media disease the formula might read for the pressure at N: musc. 40+elast. 80=120. For abnormal viscosity: musc. 80+elast. 40=120. Or again, if HN is sufficient to overcome R, which at N is 100, then musc. 100+elast. 0=100; normal being musc. 80+elast. 0=80. Thus in increased viscosity there are definite contra-indications to the exhibition of vago-depressants.

Therefore, summarising, I submit that the reasons I have given are sufficiently definite to enable me to state that in no case should the compressive power of the middle coat be artificially lowered or stimulated thoughtlessly, and that a careful distinction should be drawn between pressure due to rhythmic arterial muscular compression, and that due to simple elastic tension; and the respective shares which they have in the production of "high blood pressure."

IMMUNISATION OF THE MALTESE GOAT

BY MEANS OF CUTANEOUS VACCINATION

BY SIR THEMISTOKLES ZAMMITT, C.M.G., M.D.

AND

J. E. DEBONO, M.D.

(From the Public Health Department, Valetta)

IN a previous communication [1] under this heading we expressed the hope that a continuation of our observations would point the way to an effective protection of our goats against *Brucella melitensis* infection—the basis of our conclusion being the fact that we had succeeded in vaccinating a number of our goats to the point that they were able to withstand the subcutaneous injection of a virulent culture of *Br. melitensis* without developing an infection.

The favourable consideration of our report (which was embodied in the paper referred to) by H.E. the Governor of Malta was followed by his minute of Jan. 30th, 1931, authorising the continuation of our investigations, in consonance with which we recommenced work the first week of April, 1931, and carried on until the end of March, 1932.

PREPARATION OF VACCINE

A special avirulent strain of *Br. abortus* which had lost its power of provoking the formation of agglutinins was obtained from Dr. A. F. Huddleson of the Central Brucella station of the United States of America. This micro-organism was inoculated into flasks containing two litres of Huddleson's liver broth, which were then incubated (aerobically) for 28 days at 37° C., the resulting culture was filtered through a Chamberland candle, and the filtrate tested for sterility.

To ensure that this filtrate contained a sufficiency of the substance termed by Besredka "anti-virus," 20 c.cm. were transferred to a separate flask, and after the pH had been *readjusted to 6·8, reinoculated with the original strain of Br. abortus* and incubated aerobically at 37° C. For the next consecutive 15 days, 1 c.cm. was plated out daily on to agar. If *Br. abortus* failed to develop in the plates on any of these occasions, the filtrate was considered suitable for our purpose. The remainder of the sterile filtrate was then used to wash off the surface growth of *Br. abortus* from three-day-old agar tube cultures, in the proportion of 10 c.cm. to each tube.

This emulsion constituted the final vaccine which was put up in 2 c.cm. ampoules for use as required.

---

[1] THE LANCET, 1930, i., 1343.

METHOD OF APPLICATION

Four separate 1 c.cm. doses of vaccine were injected *tradermally* into the udders of each goat. At the ne time the udders and the mouth were sprayed th the vaccine. These procedures were repeated week later.

No clinical reaction was noticed; the goats conued to feed and to milk normally. The outstanding vantage of the method is that no agglutinins are veloped in the serum as the result of the inoculation; nsequently, if a positive serum reaction occurs bsequently in a vaccinated animal it must be due a definite infection.

We had always in mind the probability of goats coming infected through contact with infected imals, whose excreta, loaded as they usually are ith *Br. melitensis*, are in fact bound to contaminate e food and the locality, and thus there is ample portunity afforded for the specific microbe to gain entrance through the abraded skin of the healthy imals. The importance of ascertaining the truth this assumption by practical test is obvious.

Our first step, therefore, was to select 11 healthy oats that had been kept a long time under observaion and vaccinate each by our improved method, nd then to evaluate the resistance of these vaccinated oats against the chances of natural infection as ompared with non-vaccinated animals under the same est conditions.

With this end in view we formed a herd comprising the 1 vaccinated goats and 25 goats condemned by the sanitary uthorities as infected with *Br. melitensis*, together with healthy untreated animals to serve as controls, and oused it in one of the stores at the Lazzaretto.

After 16 weeks of communal life the blood of the animals was tested for the presence of agglutinins, and it was bserved that while the vaccinated goats remained negative, ne of the controls showed a very definite reaction. At the nd of this period this goat was killed, and on post-mortem xamination it proved to be very heavily infected and all ts organs yielded colonies of *Br. melitensis*.

This preliminary experiment was satisfactory in so ar as it showed that we were correct in assuming hat a healthy goat might become infected by mixing with diseased animals. We had also proof that vaccinated animals could mix with infected ones with elative impunity. On the other hand, it was unsatisfactory in that the number of control animals developing the infection was so small. The result, we noted, can be easily explained by the hygienic conditions under which our goats were kept.

Ordinary herds are usually huddled together in narrow and badly ventilated rooms, the floors of which are heavily littered with contaminated excreta and food. In our case the animals were housed in a large vaulted store with wide open arcades overlooking a well-lighted yard, so that in spite of our attempts to imitate ordinary conditions by keeping the goats together, the chances of infection were reduced to a minimum.

In order to test the immunity afforded by our method of vaccination still further we next proceeded to try the effect of subcutaneous inoculation of a virulent culture of *Br. melitensis*.

On Sept. 2nd two of the vaccinated animals used in the previous experiment and two untreated healthy animals as controls were each injected subcutaneously under the skin of the udders with a dose of approximately 100 millions micro-organisms.

After five days, blood-serum from the control goats showed a positive agglutination reaction in dilutions up to 1/80 and 1/320 respectively. Of the vaccinated animals, one remained completely negative and the other yielded a weak positive reaction in dilutions up to 1/40.

The milk from each of the four goats was repeatedly examined, and numerous colonies of *Br. melitensis* were constantly obtained from the milk of the reacting control goats. In the case of the vaccinated goats, the one with the negative reaction never showed any growth of *Br. melitensis*, whilst the other on one occasion yielded two colonies.

At the end of 62 days all the animals were killed. At the post-mortem examination both of the controls were found to be heavily infected, *Br. melitensis* being isolated from the udders, inguinal glands, and spleen; whilst in neither of the vaccinated goats could any evidence be obtained of melitensis infection.

The subcutaneous inoculation of a virulent culture is admittedly a severe test of immunity and one on an altogether different plane from that afforded by the chances of natural infection; and yet even so the vaccinated goats showed a high degree of resistance. It seemed desirable, therefore, to utilise some other method of infection, midway in severity between actual inoculation with a virulent culture and exposure to natural contagion.

Further, as it has already been shown (Eyre, McNaught, Kennedy, and Zammitt,[2] Zammitt[3]) that the kids dropped by infected dams possess sufficient immunity to resist infection by *feeding* for at any rate several weeks, we decided to utilise this method.

Accordingly, between Sept. 28th and Dec. 12th, 1931, the nine vaccinated goats still remaining from our first experiments together with 12 kids born of infected dams at the Lazzaretto, and therefore naturally immune, and four healthy normal animals to serve as controls were fed on milk which had been heavily infected by the addition of large numbers of *Br. melitensis* from agar tube cultures. After the lapse of 38 days the blood-serum from each of the four control animals gave a strongly positive agglutination reaction against *Br. melitensis* in dilutions up to 1/110, 1/320, 1/80, and 1/160 respectively. These four animals were killed, and at the post-mortem examination on Feb. 2nd abundant colonies of *Br. melitensis* were obtained from all their organs. On the other hand, all the vaccinated goats and the kids were apparently unaffected, and their serum reactions remained completely negative.

RESULTS AND CONCLUSIONS

The result of these three experiments may be set out in tabular form thus :—

Expt.	Method of infection.	Controls.		Vaccinated.	
		Exp.	Inf.	Exp.	Inf.
1	Natural contact	9	1	11	0
2	Subcutaneous inoculation..	2	2	2	1
3	Infected food (milk) ..	4	4	{ 9 12 kids	0 0
—	—	15	7	34	1

Exp. = exposed; Inf. = infected.

N.B.—In the second experiment the infection of the vaccinated goat was very mild and might very easily have been transient only—since no micro-organisms were found on post-mortem examination.

We believe that these results show that our method of vaccination is sufficient to protect goats against the mild infection, which is the rule in goats under natural conditions; and we are confident that if the goats of these islands are treated as suggested (intradermal inoculation of the Zammitt-Debono vaccine) the spread of undulant fever can be effectively stopped.

Twenty-one animals, comprising 9 vaccinated goats and 12 kids born of infected mothers (which latter we believe to be naturally immune), now remain at the Lazzaretto.

Our recommendation is that these animals should be distributed amongst herds in the country where they would be subjected to all the natural risks of infection, and kept under close observation for a period of, say, 12 months. If, at the end of that time they still retain their immunity, the value of our method of immunisation will have been conclusively established. The value of the experiment would be enhanced if an equal number of uninfected healthy goats were mixed with the same herds to act as controls.

---

[2] Reports Med. Fever Commission, 1907, vol. vi., p. 41.
[3] Jour. Roy. Army Med. Corps, 1908, x., 219.

Our best thanks are due to Dr. A. Critien, superintendent of the public health department, for having kindly placed at our disposal the P.H.D. laboratory, members of his staff, and the spare-rooms at the Lazzaretto. We have also to thank Dr. Huddleson for providing us with the special strain of *Br. abortus*, and to Surg. Lieut.-Commander Rainsford, R.N., for help during the investigation.

LYMPHADENOMA WITH RELAPSING PYREXIA

A CASE ASSOCIATED WITH ERYTHRÆMIA

By Donald Hall, M.D. Camb., F.R.C.P. Lond.
PHYSICIAN TO THE ROYAL SUSSEX COUNTY HOSPITAL, BRIGHTON

Mrs. A., aged 65, was first seen by me on Oct. 19th, 1927. She gave a history of first having had enlarged glands 12 months previously, when surgical removal had been advised and declined. Throughout 1927 she had been subject to attacks of fever, which occupied from three to five days in every fortnight, the maximum temperature being usually 102° or 103° F. (Fig. 1). The febrile period was always accompanied by breathlessness and heavy sweating, d left her feeling weak, but in the intervals she ained strength and felt well until the next attack. e stated that, apart from the febrile periods, she ad felt much better since a course of treatment by arsenic and X rays, and had required no medical advice *or treatment for several months.*

When seen, she was a well-nourished, rather pale woman with enlarged glands in the left axilla and in the left abdomen. There was no enlargement of the liver or spleen, and no clinical evidence of enlargement of the mediastinal glands. No subcutaneous nodules or hæmorrhages were present, and there was no history of hæmorrhages, except conjunctival. Her temperature was 102°, but next day it was normal and on the 21st subnormal, when she felt well and got up in her room. On the 22nd she had a relapse and the temperature touched 102° again. This, however, was exceptional, her febrile attacks from that time onwards until the terminal stage of her illness being spaced as she had described them; fortunately she had preserved her earlier temperature charts (Fig. 1). On Oct. 29th, when she was feeling well, her blood was examined by Dr. H. M. Galt, who reported :—

Red cells	7,410,000	Polymorphs	31%
White cells ..	13,100	Lymphocytes ..	67%
Hæmoglobin ..	112%	Eosinophils	2%
Colour-index ..	0·8		

In the stained films the red cells were normal in shape, size, and staining reactions.

This was an unexpected result, which was corroborated by a further count taken on Nov. 5th when she was in her next febrile attack.

She was placed under the care of Dr. W. Barrington Prowse for actinotherapy and was given arsenic by mouth and by injection in the form of sodium cacodylate, and various symptomatic remedies were employed in the hope of preventing the febrile attacks. None of them had the slightest effect, and the intermittent attacks of fever continued up to the terminal continuous pyrexia.

In December she saw Sir Thomas Horder, who wrote to me on the 16th saying that he agreed with the diagnosis of lymphadenoma.

During the ensuing weeks the external glands diminished steadily, until by Jan. 10th those in the axilla had disappeared, and on Feb. 2nd, when I had an opportunity of examining her in bed, the abdominal mass was no longer palpable. On March 24th I saw her after an interval of a month, when she told me that her last two attacks of fever had been more severe than usual, and had been accompanied by intense drowsiness. She was on that date up and about, and looking comparatively well.

On April 24th I saw her again, and for the first time felt the spleen. The liver was not enlarged; there were still no external glands to be felt, and the air entry was free and equal over the whole area of both lungs. She was persuaded to start a second course of sodium cacodylate injections. Her febrile attacks were now definitely more severe, so much so that on occasions she sent for me at the time, and I have notes of 103·6° F. on April 27th, 104° on May 21st, and 104° on June 6th, when the spleen had enlarged further, and glands were palpable for the first time in the right axilla. During the whole of this time she was up and about, leading a more or less ordinary life, refusing to give in to her malady, and even during the febrile periods by no means always staying in bed, having from long previous residence in India got into the way of disregarding what she considered (and there was no object in disillusionising her) as no more than the "fever" to which she had been accustomed in the past. It appeared now that fever in some degree was becoming constant (Fig. 2).

Dr. A. Salusbury MacNalty's report for the Ministry of Health on "Investigation of Lymphadenoma with Relapsing Pyrexia," strongly appealed to her when she was told that she was the subject of a rare type of a rare disease of sufficient importance to have been made the subject of a government research, and for the first time I was able to keep her under something approaching continuous observation. The spleen steadily increased in size, but not the external glands, although she had had no exposure to X rays since March 23rd. There was deep resistance in the abdomen in the middle line over the vertebral column, and she was troubled by bronchial catarrh, which appeared to indicate intrathoracic pressure, although clinically I could make out no dullness, and air entry was equal. She began to lose weight and strength, but on June 19th she drove up to the County Hospital and had a fifth and last blood count from Dr. Galt. This showed the same blood picture, although she was then in the terminal stage of her disease. Pyrexia was now practically continuous, and enlargement of the spleen was constant. It was, however, not until July 1st that she first complained of pain in the region of the spleen. On July 16th anasarca of the lower limbs developed. She then went rapidly downhill and died on July 21st, 1928, at the age of 66 years and 1 month.

The oldest patient with this disease in cases previously on record is said by McNalty to be a woman aged 54 years, and in his monograph[1] I find no blood counts at all comparable with those of this patient, although he has collected all cases published in the literature up to 1928. Details of the

blood counts by Dr. Galt are given in the npanying Table.

POST-MORTEM EXAMINATION

post-mortem was made at the Royal Sussex ıty Hospital on July 22nd by the late Dr. J. W. per.

e body was that of an elderly woman and, though y nourished, was by no means emaciated. There no unusual pallor of the skin, and the colour of the nal organs, mucous membranes and body fat gave no ation of anæmia. The finger-nails, lips and ears were erately cyanosed. No enlarged glands were visible ılpable in the neck, axillæ or groins. The *heart* showed erate dilatation of both ventricular cavities, but no rtrophy. There was a liberal deposit of fat over the rior surface, the heart-muscle was flabby, and beneath endocardium and on the cut surface of the myocardium e were distinct striæ of fatty deposit. Microscopical nination showed fatty infiltration, with cloudy swelling fragmentation of the muscle-fibres. The valves of the t, the aorta and the coronary arteries were healthy. blood had the normal deep red post-mortem colour, was clotted to a normal degree, the coagula being, ever, rather soft. There were no signs of capillary iorrhages in any of the organs or mucous membranes. he *liver* was enlarged, fatty and congested, with an ınced "nutmeg" appearance. The spleen was large very soft. Except for congestion of the bases the *lungs* e healthy, as were also the *kidneys*, *adrenals* and *pancreas* the whole of the *alimentary tract*. A careful search for erplasia of Peyer's patches and the solitary follicles was e negative. There were a few small subserous fibroids a pedunculated polyp of the body of the *uterus*, but erwise the pelvic organs were normal. The weights the chief organs were as follows: heart 11 oz., right g 15 oz., left lung 16½ oz., liver 72 oz., spleen 32 oz., ıt kidney 6 oz., left kidney 4½ oz. The brain and spinal l were not examined.

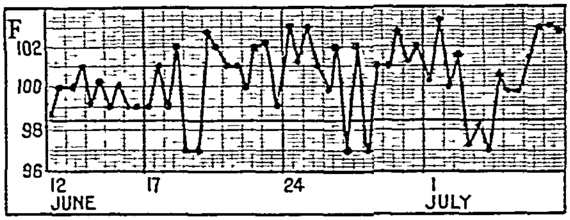
ymphatic glands.—The axillary, bronchial and retro-itoneal glands were enlarged, but the cervical and inguinal nds were not affected. In the right axilla there were e small glands and one larger one about the size of a nut. In the left axilla there were eight enlarged glands, h about the size of a small bean. All the axillary glands eared to be in a more or less early stage of the disease, l were buried deep against the thoracic wall. The arged glands in the thorax were practically confined the root of the left lung, around and below the left nchus, and had a total weight of 6 oz. The largest ss of glands was in the abdomen, extending from the ncreas to the bifurcation of the aorta, and weighing oz. No pressure effects from any of these masses were scernible.

The macroscopic appearance of the glands conformed in e main to the description of Hodgkin's disease. They were l discrete, with thickened capsules, and without any sign periglandular infiltration. There was not the slightest ıggestion of caseation or suppuration. The masses of ands were held together by inflammatory adhesions in e surrounding connective tissue. The smaller glands ere of a uniform dull pink colour, and were notably elastic ı consistency. The largest of the glands had a variable exture in different parts, elastic pink portions being admixed ith soft hæmorrhagic areas and firm white patches. A w of the smaller glands were of a dead white colour and rm consistency. In none of the glands were there any f the greyish translucent areas, or yellowish patches, ommonly described.

Sections of two of the glands were made and their histo-gical characters confirmed the diagnosis of Hodgkin's disease. One of the pink glands showed the typical replacement of the lymphoid tissue by hyperplasia of the reticulum, many of the cells of which were of the usual "lymphadenoma" type. The section of one of the firm white glands showed simply a mass of hyaline fibrous tissue containing but few cells.

The *spleen* was much enlarged but maintained its normal shape. The capsule was only slightly thickened and, as peritoneal adhesions were entirely absent, the organ was easily removed. It was very soft, indeed friable. The colour of the cut surface was a mottled mixture of irregular white areas, varying in size from a pin's head to a pea, with the intervening deep red congested splenic pulp. On microscopic examination the white areas showed an excessive proliferation of endothelial cells, arranged in alveoli separated by a fibrous reticulum, no spleen tissue proper being visible.

Fig. 2

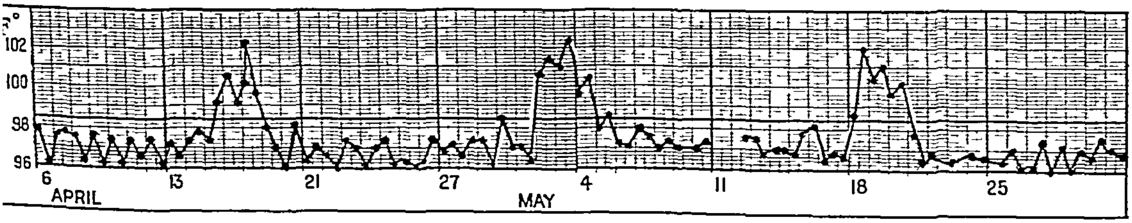


Temperature chart in June and July, 1928. Terminal type of fever.

The *bone-marrow*, taken from the middle of the shaft of the femur, was of a chocolate colour, similar to that found in other conditions in which the erythroblastic functions of the tissue have been subject to prolonged stimulation. Smears of the marrow, stained by Knyvett Gordon's method, showed abundant normal red blood-cells and a fair number of normoblasts, but no megaloblasts. There were large masses of lymphocytes, but neutrophil leucocytes were comparatively scanty, and only an occasional eosinophil and basophil were present.

The outstanding features of the post-mortem examination in this case were the absence of anæmia and emaciation, the absence of visible or palpable subcutaneous lymphatic glands, the marked enlargement and soft character of the spleen, and the response of the bone-marrow.

Fig. 1



Temperature chart during April and May, 1927, showing occasional bouts of fever.

HISTOLOGICAL REPORT

The tissues preserved by Dr. Cropper were sent to Prof. M. J. Stewart of Leeds, to whom I am much indebted for the following report:—

1. *Bronchial gland.*—The histological characters of this gland are those of Hodgkin's disease in a moderately early stage. The normal glandular architecture is entirely lost, the whole section showing a uniform collagenous reticulum with endothelial cells, small "Hodgkin" giant cells and lymphocytes, scattered about in the meshes. The giant cells are fairly numerous and very characteristic, with large, lobulated nuclei. No eosinophils are seen, but the staining is poor.

2. *Axillary gland.*—The changes here are in keeping with a much older Hodgkin's lesion of the chronic type. The gland is much and extensively fibrosed, but many endothelial cells are scattered about amongst the collagenous matrix.

Here and there are areas of greater cellularity, where, in addition to accumulated endothelial cells, there are many lymphocytes and a few Hodgkin-type giant cells. Again no eosinophils can be distinguished.

3. *Lumbar gland.*—The appearances here are quite different from both (1) and (2). The lymph-gland tissue is wholly replaced by loose cellular tissue of endothelial type, held together by a scanty collagenous reticulum. Some of the cells are of Hodgkin giant-cell appearance. The only lymphocytes seen are a few in certain narrow ill-defined fibrous septa which run through the growth. There is no dense fibrosis as in (2), but there are scattered fairly extensive patches of recent necrosis.

Spleen.—The structure is much altered, the organ showing areas which are strongly suggestive of Hodgkin's granuloma.

The *kidney* shows much post-mortem change, but nothing to suggest Hodgkin infiltration.

Liver.—There is no definite evidence of infiltration by Hodgkin's granuloma, although one small focus is suspicious. There is some patchy lymphocytic infiltration of portal tracts. The hepatic lobules are in part rather degenerate (fatty change plus early cytolysis). The most obtrusive feature of the section is the presence of many hyperplastic nodules of various sizes.

Heart wall.—The narrower section (? right ventricle) shows notable adipose infiltration of the muscle. The wear and tear pigment at the poles of the nuclei in the muscle-fibres is abundant (brown atrophy). The broader section (? left ventricle) shows, as its most obtrusive feature, extreme engorgement of the delicate, thin-walled capillaries of the outer half of the myocardium and adjacent sub-epicardial fat. The latter infiltrates the muscle slightly. "Brown atrophy" is even more marked than in the first section.

Smears of bone-marrow and spleen show nothing of note.

Prof. Stewart's conclusion is as follows: "I think the glandular and splenic changes are in keeping with Hodgkin's disease. The bronchial gland is typical of the active and moderately early stage, the axillary of the chronic fibrous stage. The lumbar gland is atypical, but still in keeping with the diagnosis. The absence of eosinophilia does not seriously discount this opinion."

SPONTANEOUS SUBARACHNOID HÆMORRHAGE

FROM CONGENITAL INTRACRANIAL ANEURYSM

By Maurice E. Shaw, M.D. Oxf., M.R.C.P. Lond.
ASSISTANT PHYSICIAN TO THE WEST LONDON HOSPITAL

In 1923 Symonds[1] drew attention to the clinical manifestations of congenital intracranial aneurysms. Before this date such aneurysms had not infrequently been noted at post-mortem examinations, but the clinical picture was not sufficiently definite to permit of diagnosis before death. Since the publication of Symonds's paper a considerable number of cases has been recorded in which a clinical diagnosis of congenital aneurysm has been made with a reasonable degree of certainty, in spite of the fact that in a number of these cases the diagnosis has not been verified at autopsy, the patients having survived. I reported such a case myself in 1927.[2]

A spontaneous hæmorrhage into the subarachnoid space is now a well-recognised condition which is easy to diagnose with the aid of lumbar puncture. Often the diagnosis may be made with considerable confidence without examination of the cerebro-spinal fluid. In young patients who show no evidence of any other disease such hæmorrhages are usually due to the presence of an aneurysm of one of the arteries at the base of the brain. If the aneurysm is so situated that it will give rise to precise localising symptoms, its position can be predicted with as great certainty as its presence. The following case illustrates the main points in the diagnosis of subarachnoid hæmorrhage; it also illustrates some of the signs and symptoms caused by an aneurysm at the base of the brain.

CASE RECORD

A married woman, aged 50, was seen at midday on April 16th, 1932, in consultation with Dr. P. C. Bhandari, at Brentford. She had been travelling home from a holiday the previous evening by road. At about 5 P.M. she stopped her husband, who was driving, and told him that she did not feel well He helped her to get out, and she rapidly became unconscious.

She was brought home by ambulance and regained consciousness during the night, but complained of severe headache which was unrelieved by the ordinary remedies. When I saw her the next day she was tossing about in bed, unable to get any relief from the pain, which was most severe in the frontal and occipital regions.

Ptosis of the left eyelid was at once obvious. On more detailed examination complete paralysis of the left third cranial nerve was found, but no other lesion of the central nervous system could be detected. All the reflexes were perfectly normal; sensory and motor functions were unimpaired, and the optic discs showed no changes. There was very slight rigidity of the neck, but Kernig's sign was negative. The heart was normal, and the blood pressure 153/85. Nothing unusual was found in the chest or abdomen.

I felt certain that a subarachnoid hæmorrhage was the cause of the loss of consciousness. The oculomotor palsy suggested that the site of the hæmorrhage was in close relation to the circle of Willis, and the possibility of an aneurysm in this position had to be considered. There was no evidence of arterio-sclerosis or other disease, such as ulcerative endocarditis, which could have caused an aneurysm. On the other hand, I thought that a congenital aneurysm would have been likely to show itself before the age of 50. Her previous history was quite negative when I first inquired about it, but on asking the husband whether he could remember any sort of attack similar to the present one he recalled that, during his absence at the war, he had been told of his wife having a "stroke" from which she had made a perfect recovery. This history completed the clinical picture, and left practically no doubt that we were dealing with a congenital aneurysm which had given rise to two attacks of hæmorrhage.

I advised her immediate removal to hospital, and she was given an injection of gr. ¼ of morphia. A few hours later she was admitted to the West London Hospital, where I performed lumbar puncture, and drew off a typical blood-stained fluid. The wisdom of performing lumbar puncture may be questioned; theoretically, it seems to me to be irrational as, by lowering the intracranial pressure, it must tend to make recurrence of hæmorrhage more likely. I confess that I was led to the performance of puncture very largely by a desire to confirm the diagnosis, which could not then be questioned in the event of recovery. Only sufficient fluid was removed to prove the presence of hæmorrhage, and morphia was given for relief of the headache and to control the restlessness.

The pulse-rate, which had been 60 before the puncture, rose to 84 afterwards. On the next day it was 44, and the temperature had risen from 99·2° to 100° F. A further lumbar puncture was performed by a well-meaning house physician without my authority, but, in view of the slow pulse, it was possibly justified. The condition certainly improved, and the temperature became normal the next day.

The improvement continued until April 25th, when the patient suddenly became unconscious and died in a few hours. Clearly another and larger hæmorrhage had taken place. During the whole time the patient was in hospital the cranial nerve palsy persisted unchanged, and no further evidence of involvement of the central nervous system made itself apparent.

A *post-mortem examination* was made by Dr. R. Elworthy. A small ruptured aneurysm was found on the left anterior choroidal artery close to its origin from the internal carotid. e under-surface of the temporal lobe was covered with ravasated blood, and a considerable quantity of blood l found its way into the lateral ventricle. This was bably the result of the terminal large hæmorrhage, the od following the course of the artery into the ventricle. e position of the aneurysm is indicated in the illustration, ich is semi-diagrammatic.

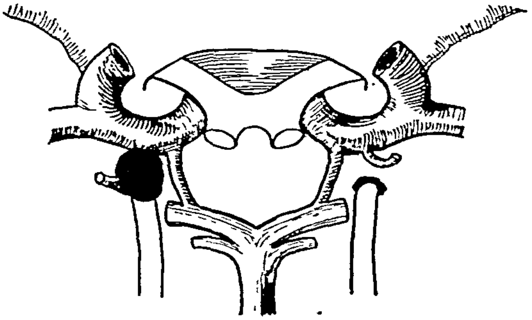
DISCUSSION

Cases similar to the one here described are probably irly common but, although the condition is oroughly familiar to neurologists, it has not yet tained the wide recognition that its frequency erits. I find that house physicians and post-aduate students regard such cases as rare, and think iat their diagnosis can only be made by a skilled eurologist. I believe that in most cases of sub-rachnoid hæmorrhage from congenital aneurysms, he diagnosis is no more difficult than that of lobar neumonia. The first essential is to keep the ossibility in mind when called to see a case of sudden oss of consciousness—especially in young patients. ubarachnoid hæmorrhage may be due to other auses, especially in older patients, but the history f its onset will always be similar. Where the hæmor-hage is not due to an aneurysm the localising signs nay be absent.



iagram showing position of aneurysm (black) at junction of *internal carotid and anterior choroidal arteries* and its relationship to the left oculomotor nerve.

In all cases of subarachnoid hæmorrhage the onset s sudden. Loss of consciousness is the rule, and lasts or a variable period. Progressive recovery, at any ate temporarily, is usual. Localising signs may or nay not be found, depending upon the source and ocation of the hæmorrhage. They vary from complete ranial nerve palsies, as in the case here described, to indefinite hemiparesis merely indicating diffuse pressure on one or other motor tract. As with any hæmorrhage into a serous cavity, there is usually a rise of temperature. The presence of the blood in the subarachnoid space causes irritation of nerve-roots, and so gives rise to varying degrees of neck rigidity, and even, sometimes, to a positive Kernig's sign. When all these features are marked, the clinical picture is very similar to that of meningitis, and there can be no doubt that in the past most of the cases were diagnosed as meningitis; where blood was found in the cerebro-spinal fluid this was attributed to carelessness in the performance of the lumbar puncture.

In point of fact, accidental hæmorrhage during puncture is very uncommon. It can only occur if the needle is pushed too far and so strikes the venous plexus on the anterior wall of the vertebral canal. Anyone with experience of lumbar puncture would know that this had happened. If any doubt exists, it can be dispelled by collecting the fluid in several successive tubes. If the hæmorrhage is spontaneous all the tubes will contain an equal admixture of blood, if it is accidental, the tubes will contain progressively less and less blood. If the hæmorrhage has taken place more than 24 hours before the puncture is performed, hæmolysis will have begun and the fluid, separated from the blood corpuscles either by centrifuging or by simply letting it stand, will have a distinctly yellow tinge. The yellow colour can be proved, by the use of the spectroscope, to be due to hæmoglobin or its derivatives. These facts are well known, but I still meet with house physicians who blame themselves for a clumsy puncture (and discard the fluid, the only evidence of their innocence!) in cases of undoubted spontaneous hæmorrhage. This mistake should not be made if the possibility of a pre-existing hæmorrhage is in mind.

The clinical features are usually sufficiently distinct to differentiate spontaneous hæmorrhage from meningitis. Reference has already been made to the signs of meningeal irritation which may be caused by the presence of blood in the subarachnoid space. The pyrexia associated with subarachnoid hæmorrhage is, however, less than is found in a case of meningitis of sufficient severity to start with the dramatic suddenness of a hæmorrhage. A sudden onset is not infrequent in cerebro-spinal meningitis, but such cases are usually accompanied by high temperature and get progressively worse during the first few days of the illness. In subarachnoid hæmorrhage the temperature is low and irregular, and the symptoms become less severe unless a further hæmorrhage takes place. Meningitis will not usually give rise to the localising signs which may be found when a hæmorrhage arises from an aneurysm. A history of a previous attack is, perhaps, the strongest evidence that can be obtained in favour of hæmorrhage and against meningitis. Congenital aneurysms quite commonly give rise to one or more attacks of hæmorrhage before one of these proves fatal.

The treatment is that of hæmorrhage in general. The only question which arises is the advisability of lumbar puncture. As a diagnostic procedure this may be necessary. As a therapeutic measure it is probably better avoided, except for the relief of a dangerously high intracranial pressure. In the latter case only sufficient fluid should be removed to restore the pressure to normal, the manometer being used. The presence of papillœdema is a definite indication for the relief of pressure but, in the absence of this sign, lumbar puncture is not desirable.

THE HYPODERMIC INJECTION OUTFIT IN PRIVATE PRACTICE

By W. E. Waller, M.D. Oxf., M.R.C.P. Lond.

The hypodermic injection outfit is perhaps the most abused portion of the physician's or surgeon's armamentarium—a statement which possibly applies with equal force to hospitals.

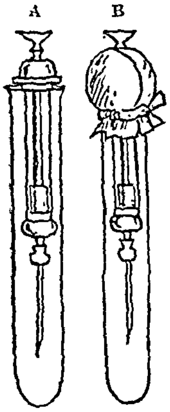
The great increase in late years of hypodermic, intramuscular, and intravenous therapy lends to the practical side of the subject a fresh interest. The increasing production by surgical instrument firms of a sequence of patterns of spirit-proof cases for the outfits and of ampoule syringes for emergency use indicate attempts to tackle some of the technical difficulties. Finally, broken hypodermic needles are not unknown, and gain prominence in the lay press.

For many years I have employed the following system in the organisation of injection apparatus, whether for hypodermic, intramuscular, or intravenous use, or for diagnostic venepuncture. The apparatus required is kept mobilised for use on a special small table, but the essential parts can, with ease and despatch, be taken on the round. Apart from the syringes and needles, the cost of the outfit is almost negligible, because it is for the most part adapted from material ready to hand.

Storage of syringes.—The following remarks apply especially to Record syringes or those of similar type. The syringe, carrying a stainless steel needle of fairly wide bore, for filling purposes only, and cleaned as stated below, is housed in a test-tube of such calibre that the barrel of the syringe can easily be inserted but the upper metal shoulder cannot (Fig. 1, A). A collar of sterile cotton-wool, completely covered by a similar collar of white lint, is fitted round the protruding part of the piston shaft below its top disc, and secured round the upper part of the test-tube below its lip, by means of a twist of bandage (Fig. 1, B.) The syringe is thus kept quite secure and dry and, suitably protected, can be safely transported in the bag and by car over rough country roads. In the surgery several syringes thus housed can be stored in a large glass sponge jar with a loose cover. This costs about five shillings. A 4 lb. jam-jar would serve equally well.

Storage and sterilisation of needles.—In a previous communication[1] I pointed out the advantages of storage and sterilisation in olive oil. Briefly the advantages are: (1) assured sterility; (2) no rusting or blocking; (3) injection made easy and as nearly as possible painless; (4) risk of break minimised from absence of rust; (5) needles do not appear to lose sharpness or temper.

FIG. 1



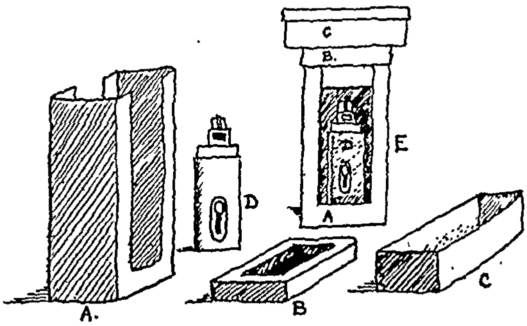
Record syringes housed in test-tubes.

The practical application is as follows. A stove is conveniently constructed from a ½ lb. Colman's mustard tin, from the front, back, and lid of which appropriate apertures are cut (Fig. 2, A and B). The aperture in front must be of such size that the introduction of the ordinary pattern of Meta fuel lamp, with its metal foot-piece detached, is possible. The steriliser itself consists of the empty plated case of a 10 minim Record syringe. This is large enough to take all sizes of needles likely to be used (Fig. 2, C). This steriliser, without its lid, is half filled with olive oil, placed on the top of the stove, and heated by the Meta lamp until boiling just starts, at which point the lamp is removed by an old pair of Spencer-Wells forceps kept for the purpose. The whole of this part of the outfit is housed in a glass dish, convenient inside measurements of which are 4½ in. long, 3½ in. broad, and 1½ in. deep. This dish is necessary when transport of the set is desired, and also from the point of view of cleanliness, since the stove and other items tend to become oily. In the surgery it is convenient to stand the dish and its contents on a plain glazed tile, 6 in. square, in no way different from the kind used in the walls of bathrooms. This is obtainable at any general store for a few pence. The stove requires cleaning with Vim from time to time, and the oil should be changed when its colour deepens.

Preparation of injection.—A second tile affords an excellent surface and carries small bottles of distilled water, surgical spirit, ether, iodine, small swabs, Meta fuel, and a small pot for expended ampoules, syringe washings, and other waste. Two other items are available—namely, (1) the inside fitting of the Record syringe case, which affords an excellent stand for the syringe (Fig. 4 simplified); (2) the metal bottom piece of the Meta lamp, which can be used as a support for ampoules (Fig. 3 simplified). A plated egg-spoon of plain pattern is added for use in dissolving injections in tablet form, and for sealing the punctures made in the rubber caps of vaccine bottles.

The syringe is withdrawn from its test-tube, and spirit drawn into it. It is then left for two minutes, supported on its stand, while the needles are sterilised and the injection made ready. The spirit is then expelled, the syringe rinsed out with more spirit, then with ether, and the piston worked till the inner surface is dry. By this time the oil will probably be boiling. The lamp is therefore removed and the filling needle sterilised by flaming, the solution being then drawn into the syringe. The filling needle is now replaced by an oil-boiled needle by means of the forceps, the blades of which are sterilised by flaming. It is advisable, when using oil-boiled needles, to leave an air bubble in the syringe, the expulsion of which will drive out oil remaining in the needle. If this is not done, blocking of the needle may occur from the cooling of the oil if the weather is very cold and if some time elapses before the injection is administered. If these procedures are carried out systematically, no oil will gain access to the interior of the syringe. The great convenience of the tiles will also become manifest.

FIG. 2



Improvised steriliser and stove. A, improvised stove with lid removed. B, lid of stove. C, steriliser without lid. D, Meta fuel lamp without its stand. E, stove, steriliser, and lamp assembled. (Scale of front objects approximately 2/5.)

After use the syringe is cleaned out by fixing the filling needle and washing out with distilled water, spirit, and ether until dry, when it is replaced in its tube. Some spirit and ether is expelled through the injecting needle, which is then dropped back in the steriliser.

Use on the daily round.—Two methods can be adopted. (1) The injection can be prepared at home, and the syringe taken to the patient secured in its test-tube. This method should not be used with serum, since there is a risk of the piston becoming glued up. (2) The stove can be stored flat in its glass dish, the Meta lamp and steriliser with its lid can be fitted inside it, and the spoon and forceps can occupy the spare space. This travels safely in the bag if kept from upsetting, though some sort of cover for the dish would be an advantage. The syringe and bottles are taken separately and appropriately protected. One of the patterns of medical bag fitted with drawers and racks for bottles is ideal for this purpose.

---

FIG. 3

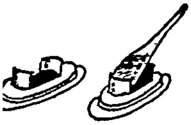

FIG. 4

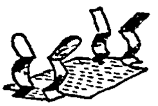

IG. 3.—Stands of Meta lamp (simplified). In the right-hand one an ampoule is shown in situ.

IG. 4.—Inside fitting of Record syringe case (simplified).

Modifications.— The system described above meets most requirements, but modifications will suggest themselves, ome of which are: (1) after use with a serum he syringe must be dismantled and washed horoughly in running water; (2) care should be aken to expel all oil from the needle when sclerosing injections are being given; (3) oil-sterilised needles hould not be used in taking blood for agglutination reactions, but can be used for blood culture work.

Rustington, Sussex.

Clinical and Laboratory Notes

CLINICAL FEATURES OF FORTY-SEVEN CASES OF INFLUENZA

BY H. L. MARRIOTT, M.D., M.R.C.P. LOND.
RESIDENT MEDICAL OFFICER, MIDDLESEX HOSPITAL, LONDON

THE following note concerns 47 cases of influenza among the staff of the Middlesex Hospital between Dec. 20th, 1932, and Jan. 10th, 1933. This, I believe, is a lower proportional incidence than has occurred in many London hospitals. The patients consisted of 36 sisters and nurses, 5 massage students, 4 maids, and 2 house officers.

The cases were of two distinct types characterised by symptoms affecting the alimentary and respiratory systems respectively. There were 7 cases of the alimentary type and 40 of the respiratory type. Within each group the manifestations were remarkably constant from patient to patient.

Alimentary type.—The symptoms were epigastric pain, nausea, vomiting, and diarrhœa. The physical signs in every case were slight to moderate tenderness in the epigastrium and slight but definite tenderness in the right iliac fossa.

Respiratory type.—The main symptom was troublesome dry cough and a sensation of tightness over the sternum; in 5 cases there was definite pain in the sternal region. As well as the cough, the patients complained of stuffy noses and slight soreness of the throat. In a few cases the fauces appeared generally red and inflamed, but in the majority the throat seemed normal. In not 1 case of the 40 were physical signs detectable in the chest.

In both types the onset was fairly sudden, and in all cases there was general malaise and aching of the limbs. The temperature ranged from 99° to 104° F.; temperatures of 102° and over were recorded in 1 of the 7 alimentary cases and in 22 of the 40 respiratory cases. The pulse-rate varied from 80 to 140. The febrile phase lasted from one to three days in the alimentary cases, and from two to nine days in the respiratory cases. In both types recovery of well-being was rapid as soon as the temperature became normal. The incubation period for either type appears to be from one to three days.

Perhaps the most remarkable feature of the epidemic was the similarity of the symptoms, signs, and course of the cases within each of the two groups; they were "like peas in a pod." No case appeared to combine the features of the two types. I have also observed the same clear-cut varieties in several score of out-patients and in-patients of the hospital. Among out-patients affected by the respiratory type of infection many had signs of bronchitis or bronchopneumonia, in contradistinction to the 40 cases domiciled in the hospital. This appeared to be due to the patients keeping about when febrile. The alimentary type of infection may easily be mistaken for an acute surgical abdominal condition, and the definite tenderness in the right iliac fossa naturally suggests the possibility of acute appendicitis.

The bacteriological aspect of these cases is being investigated by Prof. James McIntosh and Dr. L. E. H. Whitby, of the Bland-Sutton Institute of Pathology. Their investigations are not complete, but it may be stated that Pfeiffer's bacillus has been notably absent from the specimens examined.

SINGLE-HANDED METHOD OF REDUCING FRACTURES OF THE TIBIA AND FIBULA

BY PHILIP GLYNN, F.R.C.S. ENG.
RESIDENT ORTHOPÆDIC OFFICER AT LEEDS GENERAL INFIRMARY

HAVING read Watson Jones's recent paper[1] on his traction apparatus for reduction and plaster of fractures of the tibia and fibula, I wondered if there was any way of avoiding the use of the pin through the os calcis as the method of traction, at the same time employing the principle and making unnecessary the presence of a skilled assistant either to hold the limb or to plaster. The following method has therefore been devised.

The patient is anæsthetised on an ordinary operating table or trolley, the height of which it is possible to adjust. When fully anæsthetised he is pulled down the table until his legs are flexed at the knee over the edge and a sandbag is placed under the thigh as high as possible to allow the knee to hang clear of the table. The operator sits on a low stool opposite the patient's legs and the table is lowered until the ankles are at a level with his knees. The operator then grips with his knees the patient's ankle and the end of the table is raised until he feels the limit of his grip has been reached, the fragments are manipulated into position and a tight-fitting plaster is applied from the tibial condyles to the malleoli and allowed to set. The fracture is now held against anything except gross movement of the damp plaster, and the foot and thigh are plastered at leisure.

The key to the business is first the grip of the knees; and it is found in practice that the femoral condyles fit remarkably snugly into the hollow below and behind the malleoli, and the hold is quite sufficient to draw out any overlap and to hold the extension, provided that the patient is sufficiently relaxed. For those who have weak adductors it is recommended that they be supplemented by a strap round the thighs. Secondly, the plaster must be tight-fitting, especially at the prominences of the tibial condyles and malleoli. Where an adjustable table is not available the same principle, with of course not quite the fine adjustment, could be obtained by placing books under the legs of an ordinary table.

---

[1] Jour. Bone and Joint Surg., 1932, xiv., 591.

While I do not claim for this method the 100 per cent. results of the Watson Jones traction apparatus, it is a definite advance on the older method in which one person holds the limb and another plasters—a difficult proceeding even where both are skilled. The results are infinitely better. It is so simple and effective that it must have occurred to and been used by many other people; to them I offer an apology.

MEDICAL SOCIETIES

EDINBURGH OBSTETRICAL SOCIETY

AT a meeting of this society on Dec. 14th with Dr. JAMES YOUNG, the President, in the chair, a communication on the

Diagnosis of Placenta Prævia

was made by Prof. J. M. MUNRO KERR and Dr. W. G. MACKAY (Glasgow). Prof. Munro Kerr referred to the high proportion of maternal deaths due to placenta prævia, and stated that in order to maintain a low maternal death-rate it was of the highest importance that the most suitable method of treatment should be selected for each case. He spoke of the great difficulty not only of diagnosing the variety of placenta prævia but also of distinguishing between placenta prævia and accidental hæmorrhage. Any satisfactory method of differentiation would be of the greatest value.

Dr. Mackay gave a short résumé of previous investigations which had been carried out in order to locate the position of the placenta in the uterus; he came to the conclusion that the only one up to the present which had been at all satisfactory was that of Mances, Miller, and Holly, who had injected strontium iodide into the amniotic sac of pregnant women. The placenta which projected into the cavity produced a defect at the edge of the shadow when the uterus was pictured from the correct angle. Prof. Munro Kerr and Dr. Mackay had tried this method on ten cases, but as the fœtus had died in three cases it was given up and Uroselectan B, which is non-toxic and non-irritant, was substituted for strontium iodide. Twenty cubic centimetres of this substance were found to produce a suitable shadow, and in the ten cases there were no untoward effects either in the fœtus or to the mother, though there was no doubt that the injection had a great tendency to terminate pregnancy. It was necessary to take at least two radiograms, one postero-anterior and the other lateral. Those he showed at the meeting demonstrated the position of the placenta not only in normal cases, but also in cases of placenta prævia. It could be ascertained, he said, exactly how much of the placenta was in the lower uterine segment and covering the os. Sometimes it was also possible with X rays to diagnose the sex of the child, and to decide whether any coils of cord were round the child's neck.

Radiotherapy in Gynæcology

Dr. J. B. KING described the principal methods of applying radiotherapy in cancer of the cervix. He believed that the problem of the treatment of the primary lesion was solved and that the minor variations of technique now used in different clinics did not matter greatly as long as the cervix received some 4 to 5000 mg. hours suitably filtered. But the treatment of the parametrium and glands had still to be investigated thoroughly in order to improve the mortality-rate, which was even in the best statistics about 51 per cent. in early cases. Dr. King considered that the only line along which this problem could be attacked was by X ray therapy; it was certain, he said, that the highest percentage of cures had been in the clinics where X rays had been used as an adjunct to radium. He mentioned that 400,000 volts would soon be a possible dose—which was almost double the dose now available—and he thought that with this dose the pelvis could be irradiated very completely. The radium bomb might also be of use for this purpose. There was no danger in carrying out radium or X ray treatment immediately after one another in cases of uterine carcinoma, and he thought that the X ray sickness, so called, due to intensive radiation, was a thing of the past.

Dr. King then discussed radiotherapy for carcinoma of the body of the uterus and of the ovary and concluded that though radium might be of use in the former it was not likely to be of any avail in the latter. In the treatment of fibroids radiotherapy had several advantages over operation. He did not believe in the cure of amenorrhœa by so-called stimulation doses of X rays to the ovaries; for he held that no such effect as slow stimulation was caused by radiation. Successes might be attributed to destruction of persistent cystic follicles rather than to stimulation of ovarian secretion.

HARVEIAN SOCIETY OF LONDON

THE 101st annual general meeting of this society was held on Jan. 12th at 11, Chandos-street, W. The retiring president, Mr. CECIL P. G. WAKELEY, delivered his presidential address on the Rôle of Specialisation. Mr. Wakeley recognised that specialisation in medical practice was inevitable owing to the individual's inability to make himself familiar with the many and varied additions to his science and art, but in this country specialisation was characterised by certain developments which were not beneficial to the community. For example, regional specialisation in the art of surgery was largely artificial; it gave rise to various " 'ologies " which were of economic value to their practitioners but of dubious value to the patient. Again, the teaching of medicine and surgery in multiple special departments tended to divorce the student from the general principles. Mr. Wakeley contended that specialisation in hospital practice should be determined by the genius of the individual practitioner and the interests of the patient; it should not be enforced on successful candidates for hospital appointments because it was convenient to hospital administration. For the treatment of the sick he agreed with Vesalius (1543), who described the "distribution among different practitioners of the practical applications of the art" as mischievous.

Mr. Wakeley then inducted the new president, Lieut.-Colonel E. L. Gowlland, into the presidential chair. Dr. Tom Hare and Dr. Macdonald Critchley were appointed hon. secretaries, and Mr. Wakeley hon. treasurer.

CORRIGENDUM.—In THE LANCET of Jan. 14th (p. 84) Prof. Stanley Davidson was wrongly reported as saying that a preparation of solid ferrous chloride on the market costs the patient 4*s*. a day. The sum mentioned was 4*d*, not 4*s*.

REVIEWS AND NOTICES OF BOOKS

Mental Deficiency due to Birth Injuries

By EDGAR A. DOLL, Ph.D., Director of Research, Vineland Training School, New York; WINTHROP M. PHELPS, M.D., Professor of Orthopædic Surgery, Yale University; and RUTH T. MELCHER, M.A., Research Assistant, Vineland Training School. London: Macmillan and Co., Ltd. 1932. Pp. 289. 24*s*.

VERY varied estimates are current of the proportion of mental defect that is attributable to birth injury. Institutional statistics in the past have often shown very high percentages; the authors of this monograph, who betray a tendency to overstress the importance of birth injury in causation, suggest a percentage of between 5 and 10. Tredgold, although he obtained a history of birth injury in a large number of cases, rejected it as a cause except in about 1 per cent. or 2 per cent., because mostly there was also a definite neuropathic taint. The mental deficiency committee of the British Medical Association recommended critical care in the examination of any claim that birth injury is a cause of mental defect in any specific case; Dr. Doll and his colleagues, on the contrary, seem to suggest a possibility of such causation in cases where no such claim is made. The physical and mental condition of 12 cases specially studied are recorded in this monograph, the ætiology and development and the results of neurological examination and of mental and physical measurements being set out. All these were cases in which birth injury had apparently produced a permanent mental defect along with serious motor handicap, manifested usually as spasticity, athetosis, or incoördination. They cover a wide range of age of both sexes, including all grades of defect up to the borderline.

The authors propound more problems than they solve, and the work lacks positive results. One of the main objects of the investigation was to discover how far it is possible by physical therapy to improve not merely the motor condition of the subjects but also their mental condition. Dr. Doll and his collaborators are their own severest critics when they admit that it was not possible adequately to measure either the mental or physical improvement during a period of treatment which they admit, moreover, was too short. Growth processes coinciding with the treatment interfered with the assessment of results, and while some increase of mental alertness and improvement in social functions were noted, a careful study of the detailed descriptions fails to reveal any improvement of substantial value to the individuals concerned. In the course of the inquiry it was found necessary to attempt to estimate the value of certain types of mental tests in assessing these subjects. The Stanford-Binet scale seemed to be less affected than were other tests by handicaps of speech and motor control, and lack of experience and training. The authors claim to have demonstrated that birth-injured cases tend to show a type of development which continues beyond the usual age of maturity, so that early retardation is offset by the prolongation of later development. So wide an inference, however, can scarcely be based on the study of a few cases. There is much repetition in the book, and, from the reader's point of view, the arrangement by which he has to search through four different sections of the book, including an appendix, to obtain a complete account of any one case is not convenient. It is to be hoped that the investigation, which is being continued, will later be more fruitful of positive results.

Mechanism of Creative Evolution

By C. C. HURST, Ph.D. Cambridge University Press. 1932. Pp. 365. 21*s*.

Recent Advances in Plant Genetics

By F. W. SANSOME, Ph.D., and J. PHILP, B.Sc. London: J. and A. Churchill. 1932. Pp. 414. 15*s*.

Recent Advances in Cytology

By C. D. DARLINGTON, D.Sc., Ph.D. London: J. and A. Churchill. 1932. Pp. 559. 18*s*.

MAN has been moulded by variation and natural selection. He has advanced beyond brute beasts by his capacity to control his environment, and live, to some extent, under conditions which he chooses himself. In this way he has had an influence on natural selection, qualitative and quantitative, and he has so arranged his surroundings that moral and spiritual as well as carnal qualities have their values. But he has taken very little deliberate action to arrange himself, and the practical purport of these three books is to explain that the great advances which have been made in genetics in the last 30 years have put him into the position of being able to add a cubit to his stature if he wants to, and to surround himself with animals and plants which are to his liking. This is the professed argument of Dr. Hurst's book, which is clear, readable, beautifully illustrated, and cheap; it expounds plainly the doctrine (or fact) that the differences between the species and varieties of live organisms depend on differences in the genes in the chromosomes. The other two are more detailed and technical, and are hardly for general reading. Dr. Sansome and Mr. Philp, who work at the John Innes Horticultural Institution, describe the recent work on plants, and have a final general chapter which we could wish was longer. Dr. Darlington, of the same institute, deals with the same topics in a more general way; his book is for the serious student and the title is quite misleading, for there is practically nothing about any cellular constituent except the chromosomes. Those who are interested in mitochondria and the Golgi apparatus may be disappointed.

La polypose recto-colique

By Dr. PIERRE AUGIER, Chef de Clinique à la Faculté de Médecine de Paris. Paris: Baillière et fils. 1932. Pp. 282. Fr.40.

THIS monograph provides an exhaustive clinical and microscopical study of polyposis of the colon and rectum. The most important type of the disease is described under the name of essential polyposis, which corresponds to the term polyposis intestini, as generally accepted in this country. Every aspect of the ætiology and symptomatology is considered in detail, and the peculiar association with polyposis of two other conditions is noted—one being clubbing of the fingers without cyanosis or venous dilatation ("hippocratisme digital"), and the other "intestinal infantilism," the significance of which is discussed, and is to be further investigated more fully. In Chapter IX. the relationship between polyposis and cancer is debated; the author reports that in 110 cases which he has analysed, malignant degeneration, verified at operation or post mortem, was proved to have taken place in 37 cases, or 33·6 per cent. Other forms of polyposis, such as that associated with bilharzia infection and the inflammatory type of polyposis, are also described. Treatment varies with the type of the disease; the indications for electrocoagulation, radiotherapy, and major surgical operations, such as colectomy, are all discussed. Case reports of 121 cases of polyposis are appended.

This monograph clarifies and consolidates our present knowledge of polyposis of the colon.

An Atlas of Skin Diseases in the Tropics

By E. C. SMITH, B.A., D.P.H., D.T.M. & H. Eng., Pathologist, Medical Laboratory Service, Nigeria. London: John Bale, Sons and Danielsson, Ltd. 1932. Pp. 60. 100 plates. 21*s.*

THE text of this useful atlas is brief; it does not compete with standard works on dermatology. It is primarily intended for the use and reference of tropical practitioners, whose daily work will doubtless bring them into contact with many of the dermatoses herein described and photographically illustrated. As regards illustrations, the book is a real treasure, for none of them appears to be borrowed, and every one is a technical success, the result in part, no doubt, of the pigmented background, against which the lesions stand out like the mountains in a relief map. The photographs and microphotographs demonstrating experimentally produced prickly heat (miliaria papulosa) and with a monilia as the alleged cause will certainly arouse comment. Hitherto a staphylococcus has been generally accepted as a factor, but Dr. Smith has succeeded in producing the typical eruption in from 5 to 12 days by local application of strong broth cultures of the monilia. A further observation of much interest and possible significance relates to the prevalence of melanotic sarcoma, stated to be "by far the most common malignant growth," usually on the foot, among natives. Dr. Smith is doubly qualified to write a book of this kind, for not only has he had clinical experience, but is a trained pathologist, writing most of the time with one eye to the microscope. This pathological approach, together with the admirable illustrations, should ensure the success of his atlas.

Excitability: A Cardiac Study

By W. BURRIDGE, D.M., M.A. Oxf., Professor of Physiology, Lucknow University. London: Humphrey Milford, Oxford University Press. 1932. Pp. 208. 16*s.*

THIS book is difficult to read and to understand. In it are recorded and correlated the results of a long and carefully carried out series of experiments aiming to elucidate the problems of excitability and contraction in muscle, particularly in heart muscle. Using the isolated heart of the frog, Prof. Burridge has tested its reaction to various reagents, as unusual as 40 per cent. alcohol and 5 per cent. KCl. From his results, which are undoubtedly interesting, he attempts to unravel the mysteries of the function of heart muscle, but only succeeds in making it more difficult to understand. He further obscures the issue by entering the field of metaphysics to obtain support for his contentions, and throughout the work steps lightly from this muddy walk of physiology to the still muddier fields of psychology, a feat likely to have a shattering effect on the reader's intellectual processes. For example, his conception of mind as a sort of frothy by-product of the metabolism of nerve-cells is based on no more solid ground than the argument that as contraction of muscle-fibre is a phenomenon in two phases, so a nerve-cell must be possessed of a material and a metaphysical function. The literary style is as original as the matter, but there is an unfortunate tendency to repetition, and a too frequent use of metaphors.

Minor Surgery

Second edition. By FREDERICK CHRISTOPHER, S.B., M.D., F.A.C.S., Assistant Professor of Surgery at the Northwestern University Medical School, Chicago. London: W. B. Saunders Co., Ltd 1932. Pp. 996. 50*s.*

THE new edition of this popular book confirms the high opinion we formed of it when it was first issued. Much new matter has been added to bring it thoroughly up to date. A vast area of knowledge is included in the term minor surgery. The author of a book designed to cover this area can either confine himself to the methods actively practised by himself, or can select from his own and the published experience of others those methods which appear to give the best results. The latter procedure, which has manifold advantages, has been adopted by Prof. Christopher. His descriptions are the more useful since he supplies the sources of information which have guided him in his choice. This is a valuable book, providing a most reliable guide for the house surgeon. Practising surgeons will find within its covers much information that could only be collected by arduous and time-consuming search of surgical literature.

Lunacy Accounts

By T. C. S. KEELY. London: Jordan and Sons, Ltd., Chancery-lane, W.C. 1932. Pp. 79. 7*s.* 6*d.*

EQUIPPED with long experience in the office of the Masters in Lunacy at the Royal Courts of Justice, Mr. Keely has written a short book on lunacy accounts which will be useful to those who, as trustees or receivers, are responsible for the affairs of a mental patient. If lawyers, they may know the relevant Acts and cases, but may have something to learn about the most acceptable method of presenting accounts and about the department's attitude towards particular items of expenditure. If laymen, the information (and the specimen accounts) will be all the more valuable. Will the Master, for example, sanction allowances from surplus income to the patient's wife and family, poor relations, and old servants? Will he authorise the continuance of the patient's club subscriptions? What may properly be included under "Miscellaneous Expenditure"? Mr. Keely answers these and similar questions. He advises us not to put down a round sum for miscellaneous expenses—not because the department wants to be niggardly, but because a receiver should not charge for such items more than he has actually spent. Nowadays the department, in reviewing the management of a patient's estate, wants more than mere columns of payments and receipts. It may ask about his housing, care, and comfort, his capacity to enjoy outings, amusements, and little luxuries, the desirability of moving him, and whether any special course of training or treatment, surgical operation, or dental attention is required. Mr. Keely assures us that the department welcomes suggestions for the benefit and advantage of a mental patient, and gives effect to any which are found possible and desirable.

THE LANCET

LONDON: SATURDAY, JANUARY 21, 1933

THE PROBLEM OF CONVALESCENCE

Acute illness appeals to the imagination both of the patient and of those who have the care of him. It is, as Charles Lamb remarked,[1] a magnificent dream for a man to lie a-bed, and draw daylight curtains about him, to become insensible to all the operations of life except the beatings of one feeble pulse, to be a giant of self-importance who swells in the sole contemplation of his single sufferings—epitomised by Lamb in the phrase "the puffy state of sickness." The treatment of acute illness has been developed into a state of great efficiency; outside Ford's works there is probably nothing much more efficient than the team of an operating theatre with its quiet concentration on essentials of life and death. But, as Lamb remarks, how convalescence shrinks a man back to his pristine stature. Even the visitations of the medical attendant have changed. Can this be he who so lately came between the patient and his cruel enemy, as on some solemn embassy from nature? This man of news, of chat, of anecdote. "Pshaw!" says Elia, "'tis some old woman." And it is a matter of everyday experience that the treatment of the convalescent, being further from the centre of interest, lacks the care and attention which it deserves. We know, for instance, with rather insistent accuracy, the risks of childbirth; but no one can more than guess the extent to which he chronic illness which it leaves in its train cripples the happiness and efficiency of domestic ife. The patient is treated adequately in hospital or, let us say, pneumonia or some surgical emergency. He goes out "cured"; and indeed every effort is made to speed the parting guest, for the unning cost of hospitals is necessarily high. But his discharge from hospital may be delayed beyond the time when he requires such special attention because of the fear that he is unlikely to regain at home the fitness to resume his daily avocation. He may be left with some respiratory infection, with debility, and some slackness of the abdominal muscles, and because in our present system the means are lacking of securing for him complete convalescence and a return to full vigour, these disabilities persist too long or result in some degree of permanent unfitness. There are many directions in which the same conclusion is reached. In a discussion at the Liverpool Medical Institution, reported in our last issue, Dr. H. E. Moore, speaking as a railway surgeon, made it clear how much of the wastage resulting from industrial injuries is avoidable; for, he said, if only proper treatment had been given at an early stage, many instances of long incapacity might have returned to their former occupations in quite a short time. Surgical supervision, adequate at the start, becomes too spasmodic to be effective, and he counselled the setting up of traumatic centres throughout the country controlled by orthopædic surgeons of experience and providing free facilities for insured persons whose convalescence from injuries was proving tardy. It was pointed out in the same discussion how, in the presence of a minor disability, allowed to remain after an injury, even a keen worker was prone to fear the moment of his return to work, from the feeling that his incapacity might increase and lead to discharge on the grounds of inefficiency. On this account even trivial injuries are apt to cause undue delay in returning to full work.

Convalescence has been paraphrased rather neatly as the after-treatment of hospital patients, and the problem is not to be solved by prolonging the stay in hospital, for quite apart from expense it is undesirable for the patient's psychical condition for him to stay longer than necessary. The difficulty is world-wide. From a letter by Dr. G. Kahlmeter to the *Archives of Medical Hydrology* (January, 1933, p. 121), it is clear that in Stockholm large numbers of patients are retained unduly long in hospital owing to the difficulty in placing them. They ought to leave sooner for, Dr. Kahlmeter tells us, the hospital atmosphere makes them depressed, and the difficulties—not to say aversion—which they experience on returning to their old work and home surroundings become greater with lapse of time. On the other hand, if sent home too early they are as a rule forced immediately to resume work which is beyond their strength at the time, and the benefit derived from the hospital treatment is thus nullified and their general condition aggravated, or the malady relapses. Many patients are instinctively afraid of this, with the result that their mental state during the latter part of their period in hospital is often disquieted by worrying about too early a discharge. It will be noted how closely Dr. Kahlmeter's experience agrees with that recorded by the Liverpool surgeons. How is this awkward period between hospital discharge and resumption of work to be filled in to the best advantage of body and mind? It should not, as we have seen, be spent in the hospital atmosphere, nor is the return to unsupervised home life any nearer the ideal. Most of our experience of the means of filling up this interval has been gained from the experience of institutions where the interval is so long that something has to be done about it. In the prolonged convalescence of mental disease and of acute tuberculosis great centres have arisen in which treatment of one kind or another has been tried out. Some of the county mental hospitals from time immemorial have been setting the employable patients to tasks fitted to their condition, and yet of a sufficiently interesting and productive character to engross their attention and make them feel a growing sense of responsibility for their own lives. In the treatment of phthisis the same tendency may be seen to make the conditions of convalescence resemble more and more closely those of domestic or working life lived under supervised conditions. It is curious how the industrial colony, under one or other name, has arisen as the spontaneous idea of a sanatorium director, impressed by the results of relieving the physical results without considering the mentality of the patient.

---

[1] The Last Essays of Elia: the Convalescent.

But it is all too evident that in these straitened times the means would not be available for such residential treatment of all ex-hospital patients, even if it were desirable. Convalescent branches in the country are attached to many metropolitan hospitals, and Edinburgh has an example of what can be done in systematising an institution for efficient convalescence. More institutions of this kind there should certainly be, but in the meantime it remains for us to devise under simpler conditions what Dr. Kahlmeter wisely calls "qualified convalescent treatment." In the hospitals it involves the creation of a social service department as a unit complementary to the medical, surgical, and pathological units of the hospital, and outside the hospital it implies additional facilities for the general practitioner who is at long last the only judge of whether a patient is or is not restored to his normal working capacity. It is difficult to think that the need can be completely met other than by the formation of general practitioner clinics, and once again we come back to the proposals of the Dawson report of 1920, which, like those of the Golden Rule, have not been discredited, because they have never yet been put in practice. The primary health centre, foreshadowed in that report, was to be an institution equipped for services of curative and preventive medicine, conducted by the general practitioner of the district, in conjunction with an efficient nursing service and with the aid of visiting consultants and specialists. Among the equipment there would be baths, apparatus for physical culture, and so forth—in a word, convalescent treatment; with the addition of the occupational therapy as generously defined by Dr. Norah Haworth on p. 171 of this issue. Liberally construed, these primary health centres might develop into recuperative centres, serving the double purpose of restoring patients to health after illness or before their illness has become disease.

HORMONES AND MENSTRUATION

The attention of the general reader is being drawn more and more insistently to the sex hormones. Even within the last few months a further liveliness has been apparent on the physiological and biochemical front, and every few weeks we are confronted with fresh and well-authenticated statements that would have seemed incredible a few years ago. Prof. Walther Schoeller's review in our issue of Jan. 7th illustrated this progress and showed once more that here is one of the most exciting and promising branches of research. At the same time it did not disguise that as yet there has been more promise than performance, so far as clinical medicine is concerned. Looking at Prof. Schoeller's pictures the practitioner must have wished that his patients were potted hyacinths or lilies and would benefit accordingly by small doses of his elixirs. But the gulf even between man and the rabbit remains a wide one, and meanwhile one must recognise that though progress in laboratory experiment has been clear-cut and continuous, the application of the experiments to clinical work has been far from satisfactory. Apart from the very valuable Aschheim-Zondek reaction, the laboratory methods have been more or less a failure when applied to gynæcological diagnosis. On the therapeutic side there is such a mass of conflicting evidence that it is almost impossible to arrive at any definite conclusion. One school of workers, for example, maintain that the action of the follicular hormone (œstrin) obeys the definite body-weight ratio rule, and hold that thousands of units would have to be administered to a woman before any results could be expected. Another school, on the other hand, claim to have achieved definite results by means of small doses of this hormone administered subcutaneously. The difficulties in interpreting any results of this type are very real. In the treatment of any form of amenorrhœa, for instance, the possibility of spontaneous menstruation is so great that it cannot be ignored; while improvement in subjective symptoms, such as those of the menopause, renders quantitative observations impossible.

Œstrin is, by definition, the œstrus-producing hormone *—that is to say, it will induce an œstral cycle in castrated animals. It might be thought therefore that it would induce menstruation in women, and it has, in fact, been used with this object. But œstrus and menstruation are far from being synonymous, and work on monkeys has shown that bleeding induced by injections of œstrin is merely hæmorrhage from an "interval" type of endometrium. Immediately after menstruation, it is believed, the ovaries are inactive and the endometrium is at rest. From about the tenth to the fourteenth day (the "interval") the ovaries contain ripening follicles and the endometrium is hypertrophied—this hypertrophy being attributed to the secretion of œstrin. Then comes the premenstrual or corpus luteum phase—far more prominent in man than in other animals—when the endometrium prepares itself, under the influence of the corpus luteum, for nidation of the ovum. Failing conception, degeneration of this proliferated epithelium takes place and is manifest as menstrual loss. And if this theory is correct it is necessary, in order to produce artificial menstruation, not only that the uterine mucous membrane should be sensitised by the follicular hormone, œstrin, but also that it should go through a pregestational stage under the influence of another ovarian hormone, the "progestin" poured out by the corpus luteum. Prof. Schoeller mentioned that menstruation had now been produced by these means in the human female after double oöphorectomy, and Dr. C. Kaufmann's account of this important experiment has just appeared.[1]

---

* Preparations of the follicular hormone, œstrin, are sold under the names of theelin, progynon, menformon, and sistomensin.

[1] Zentralblatt f. Gynäk., 1933, No.1, p. 42.

The patient was a woman who had both ovaries removed five or six years ago, at the age of 17, for dermoid cyst. Her periods had previously been regular. In the middle of October last he began to treat her daily with progynon benzoate—a preparation of œstrus-producing hormone—intramuscularly; and from Nov. 10th to 18th he also administered 10 rabbit units every day of luteal hormone (Schering-Kahlbaum A.G.); the total dose was 320,000 mouse units of progynon and 90 rabbit units of corpus luteum extract. In 24 hours after the last injection of luteal hormone bleeding began. The total quantity in the first day was 20 c.cm. of a viscous, dark red blood in which no epithelial debris could be seen microscopically. When removed after 36 hours the pessary contained a large fragment of tissue which proved to be a piece of uterine mucosa. Bleeding continued for another 30 hours, and the total quantity lost was 40 c.cm.

Dr. KAUFMANN claims, from the microscopical examination, that the bleeding was a genuine menstruation. He points out that the success of the experiment depended on the large amounts of hormone used, the dose being determined from former estimation of the quantity present in the urine of healthy women.

These may seem small matters, if looked at without the eye of faith. But it has to be remembered that the substances now being used in small doses are no longer utterly obscure in constitution, and therefore far beyond control. This was evident from the tentative formulæ we printed a fortnight ago, and even in the short time since then there is news of a notable new advance. In a letter to *Nature* (Jan. 7th), Mr. J. W. COOK, D.Sc., Prof. E. C. DODDS, and Mr. C. L. HEWETT, of the research institute of the Cancer Hospital and the Courtauld institute of the Middlesex Hospital, state that they have found, for the first time, a synthetic organic compound, of know constitution, which has definite œstrogenic properties. On the hypothesis that the follicular hormone or hormones are formed by degradation of sterols they took as the starting-point of their investigations 1-keto-1 : 2 : 3 : 4-tetrahydrophenanthren. Though feeble in comparison with œstrin, this proved capable of producing œstral reactions in castrated rats. The importance of this is obvious; but it may be more important even than it seems. Not only has this substance, in its molecular structure, points of resemblance to that suggested for ketohydroxy-œstrin, but in the opinion of these workers it may also form a bridge between the sex hormones, the carcinogenic hydrocarbons, and substances of the fused-ring type, such as cholesterol and vitamin D.

◆

MINERS' NYSTAGMUS

IT might have been expected that the questions connected with miners' nystagmus would long before now have been settled. Two reports on the subject by a committee of the Medical Research Council were issued in the years 1922 and 1923. The principal finding of this committee was that the chief symptom of the disease—namely, involuntary oscillation of the eyeballs—was caused by an insufficiency of the light reaching the eyes of the miner while at work, and that of all measures of prevention the most important was to secure for the miner at work an adequate illumination. The Medical Research Council have meantime found it advisable to reconstitute this committee, and they have now issued a third report[1] which deals with the situation as it exists to-day. The alarming fact which the committee have had to face is that in spite of a considerable improvement in the illumination of the mines which has been secured in accordance with the recommendations of the first committee, the incidence of the disease known as miners' nystagmus, as judged by the numbers of those who have been awarded compensation, has, on the whole, steadily increased, the total number of persons to whom compensation was paid having increased from 1618 in 1910 to 7028 in 1920 and 10,638 in 1930. In essaying to account for this formidable increase, the present committee are firm in their support of the main conclusion of the former committee, that the fundamental cause of miners' nystagmus in the narrower sense of the term—i.e., oscillations of the eyes—is the low illumination under which miners in general work, and they adduce weighty evidence to prove that in several mines where a defective system of lighting has been replaced by an adequate system, the results have been so favourable as to confirm this view, and to encourage the policy of introducing improved lighting in all mines where the workers are subject to nystagmus. To account for the actual increase in the "disease known as miners' nystagmus" it is necessary to look in an altogether different direction—namely, to the fact that the disease, as officially defined for purposes of legal compensation, consists not only of eye oscillations, indeed may exist without any eye oscillations at all, but, whether combined with or apart from that particular symptom, is made up of various "nervous" symptoms, some of them connected with the eye, such as photophobia, night-blindness, or temporary loss of visual acuity, others wholly apart from the eye and akin to those with which the Great War made us familiar under the terms "shell shock" or "disordered action of the heart." As the report puts it: "it is not sufficiently recognised that the attribution of nervous symptoms to a physical cause is a probable factor in the evolution of the compensated disease." Owing to the apparent negligence with which the definition of the disease entitling to compensation has been framed, there has been a fatal tendency to slipshod diagnosis, and unfortunately the prospect of securing compensation has undoubtedly acted as an encouragement to the patient to make the most of his symptoms.

The outcome of the investigation is that so far as oscillation of the eyes is concerned this symptom has been proved to be connected with an insufficiency of light while at work. The phenomenon is based on the fact that in a condition of complete dark adaptation the peripheral parts of the retina are more sensitive than the central parts and the habit of macular fixation may be suspended or even lost. It is found however that even in cases where nystagmus is fully developed there is not necessarily incapacity. Frequently miners with oscillation remain at work entirely unconscious of their condition. In many cases, on the other hand, oscillation of the eyes involves apparent movement of objects, with dizziness and headache. If the disability remains at this stage the question of psychoneurotic factors does not arise. Often however it does not stop here, further developments occur, and what at first sight seemed to be an ocular disorder pure and simple takes on the aspect of a psychoneurosis—i.e., a condition which may be one of actual disability but one not amenable to modes of treatment familiar to the ordinary medical practitioner, and requiring knowledge of psychoneuroses in general and experience and tact in dealing with them.

---

[1] Third Report of the Miners' Nystagmus Committee. Medical Research Council: Special Report Series No. 176. H.M. Stationery Office. 9d.

The report is accompanied by two appendices, the first by Prof. Millais Culpin containing an analysis of 36 cases receiving compensation examined by himself, in which he has made note of the nervous conditions of the patients. In only 3 of these cases was oscillation evident while the patient was being talked to. In 11 it could be elicited by special motions of the eyes, and in 22 it was not seen at all. In almost all there were psychoneurotic symptoms such as irrational fears, present to a greater or less extent, and in this connexion Dr. Culpin points out that in coal mining the danger that actually exists of explosions and other catastrophes, may prey on the minds of some men more than others, making them peculiarly liable to a "nervous breakdown" of some sort, just as the terrible conditions to which soldiers in the trenches were subject rendered some more than others liable to "shell shock." Only in two cases did he suspect actual malingering, and this fact is important as otherwise the uninstructed might fail to realise that these nervous symptoms actually do involve a disability calling for proper treatment. The important point is that treatment to be effective must be mental, and that to provide hope of compensation dependent on continuance of the disability is the very worst form of mental treatment possible. This point is further illustrated in the second appendix by Dr. T. L. Llewellyn. "The incidence of miners' nystagmus in individual pits is very irregular," he says, "and is largely influenced by conditions of unrest, local dispute, and custom. The looseness of the scheduled definition allows the inclusion of men either not suffering from the disease or not incapacitated by the disease." As to the good effect of improved lighting there can be no doubt. Between 1920 and 1928 the proportion of electric to oil lamps was increased from 28·0 to 47·0 per cent., but that was not enough. A poor electric lamp is a worse source of illumination than a poor oil lamp, and whole installations of electric lamps have been rendered useless by lack of attention to batteries. In many cases the electric lamps gave a poor light and did not last the shift out. More recent reports of mines where electric cap lamps have been provided or electric hand lamps of as much as 4·5 candle power show much more favourable results.

The main recommendation of this important report, in its final words, is "that the practical treatment of the disease, from an administrative point of view, should consist in the elimination of a hopeless dependence on compensation by the provision of opportunities for work of some kind, the end in view being complete restoration to full work underground, under conditions of proper illumination, even if this has to be preceded by a period of work in daylight."

COLDS AND INFLUENZA

Influenza is once again in our midst; the season of the common cold is reaching its acme. Such a time is a propitious one to pass in review the endeavours which are being made to gain a more intimate knowledge of these conditions. And since so much turns on a precise understanding of the ætiology of any disease it is this aspect of the problem which should concern us primarily. In the past, as was only natural, investigations into the causation of the common cold were largely concerned with the incrimination of a cultivable bacterium. There has been no lack of these; the choice was embarrassing, as the composition of the anticatarrhal vaccine testifies. But no cultivable bacterium has been isolated from coryza, which was at once peculiar and common to all cases of this disease, and with the exception of man there was no suitable experimental animal on which to try out the various claimants. Further, the common cold, from the clinical point of view, appeared to be an entity, and this suggested that the different bacteria present in the nasopharyngeal discharge were merely secondary invaders, and that the prime cause had yet to be found. This impasse gave birth to the view that a filtrable virus was to blame, a view which recent work has gone a long way to confirm, and although Dochez and his colleagues in America were not the first to endeavour to provide experimental proof of this hypothesis, the thoroughness and care with which they approached this problem makes their work a landmark in this field of research.

Readers of The Lancet are already familiar with the work of Dochez,[1] and there is no need to review it again in detail. Suffice it to say that he and his colleagues envisaged in turn the ætiological significance of cultivable aerobic bacteria and filter-passing anaerobes, only to discard them; and then proceeded to demonstrate the possibility of reproducing typical colds both in chimpanzees and human volunteers by means of the filtered nasopharyngeal washings from spontaneous cases. P. H. Long and a team of workers[2] at the Johns Hopkins University have repeated these experiments using human volunteers only, and obtained similar results; and more recently C. H. Andrewes and

[2] Long, P. H., Doull, A., J. Brown, J. M., and McComb, E.: Jour. Exp. Med., 1931, liii., 447.

W. G. Oakley,[3] at St. Bartholomew's Hospital, have had a like success. They, too, made use of human volunteers, and tested in all the filtered nasal washings from ten people with colds. Of these filtrates five proved active, and with them they produced typical colds in 15 out of 36 men inoculated, a proportion of success closely approximating that obtained by Dochez and by Long. Andrewes and Oakley were, however, unable to confirm Dochez's claim to have cultivated the virus. Cultures made by them according to Dochez's technique proved inactive when tested on 24 volunteers; and even Dochez, who came over to this country at the time, bringing with him his own cultures, was not any more successful, so that his claim to have grown the virus cannot yet be accepted. Yet the main portion of his work stands intact. The prime cause of the common cold is a filtrable virus.

With influenza progress has been less satisfactory. The difficulties encountered in the experimental investigation of the common cold are not less in the case of influenza; in fact they are even greater. The use of human volunteers in work on the common cold is one thing, their use for influenza quite another. There are several ætiological claimants in the field—filtrable virus, *Bacterium pneumosintes*, Pfeiffer's bacillus—the difficulty is to decide between them, and unless a suitable experimental animal is found progress will be held up indefinitely. With regard to specific prophylaxis in these two diseases, it must not be forgotten that the natural disease does not appear to confer much immunity—at best it is only short-lived—so too much must not be expected from artificial measures. There remains, however, prophylaxis against the secondary invaders which play an important part, especially in influenza, and this is catered for by the vaccines already in use.

ANNOTATIONS

DRUG AND ALCOHOL ADDICTION IN GERMANY

Until recently Germany has had a somewhat heavier drug problem to deal with than Great Britain, possibly because of her large land frontiers and possibly because of a temperamental factor. Dr. Paul Wolff, one of the two editors of the *Deutsche medizinische Wochenschrift*, who does much work on the drug and alcohol problem for the League of Nations, told the Society for the Study of Inebriety on Jan. 10th of the far-reaching effects of the new ordinance which came into force on April 1st, 1931. Statistics published in 1928 indicate that Germany had between 4000 and 6000 addicts out of a population of about 64,000,000, and that this figure included about 500 doctors. Germany has not the provision which this country has for depriving a doctor who is an addict of the right to prescribe dangerous drugs, but a measure to this effect is expected. The ordinance of 1931 restricts the right of prescribing opiates, and compels a doctor to keep a record of a larger prescription than 0·1 g. of morphia or 2 g. of opium daily. Heroin, which in Germany is called diacetylmorphine, seems to play very little part in that country; for some reason it has no attraction for the would-be addict. The law discriminates in favour of suppositories as against injections. Since the promulgation of this ordinance the consumption of morphia has been reduced by about 20 per cent. and that of opium by about 30 per cent. Similar restrictions aimed at the use of cocaine have resulted in a decrease of 50 per cent., and an additional drop in consumption is expected when the 1932 figures are available. Its use is confined now almost entirely to ear, nose, throat, and eye operations, subject to certain provisos. The pure substance is no longer supplied to the medical profession, and specialists have found that the modern substitutes are equally efficacious. Dr. Wolff states from personal observation that the illegal drug traffic in Berlin is very much on the wane.

The German authorities have also made a determined attempt to reduce alcoholism. The Licensed Premises Act of July, 1930, imposed restrictions on the granting of licences, defined opening and closing hours, and provided for the prohibition of the sale of spirits at certain times, such as pay-day and election days. The chief object of the measure was to prohibit the sale of alcohol to persons under 18 and intoxicated persons, and the sale of tobacco to children under 16; also to stop the practice of charging extra for meals at which no alcohol was drunk, and to forbid the sale of spirits on sports grounds and in gymnasia. The present consumption of spirits in Germany is only 20 per cent. of what it was in the first decade of the century, and the consumption of beer only 31 per cent. Chronic alcoholism is on the downward grade and delirium tremens has become very rare. The mortality from alcoholism in German hospitals is about one-third of what it was before the war. The whole treatment of inebriety throughout the country is systematically organised through the various temperance societies, and is carried out both in general hospitals and in special institutions administered by the State. Particular importance is attached to treatment in the early stages. The draft of the new German Penal Code contains provisions whereby a judge can enforce a withdrawal cure and order supervision of an inebriate. One of the best prophylactic measures, Dr. Wolff remarked, has been the raising of the price of alcoholic liquors by taxation in proportion to the alcohol content.

PROBLEMS OF DEVELOPMENT

All who are interested in fundamental biological problems, or are concerned with their bearing on related questions, should consider the authoritative work of Bernhard Dürken which has recently been made available in English.[1] Prof. Dürken is a supporter of the *Einheitstheorie*, and it is his subtle analysis of the claims of opposed views about the development of the organism which is of special interest. We have been presented in recent years with such exact experiment and accurate forecast by the geneticists and investigators of heredity, that almost unconsciously we have come to look upon the development of the whole organism as in the keeping of chromosomes, built up of genes which are the actual producers of the various characteristics. The idea of the chromosomal ordering of the organism from its commencement, however, has not seemed entirely satisfactory. It does not fit in with the facts of wider experience: for example, such phenomena as sex-reversal, regeneration, and the results of experimental transplantation and the like on young embryos were apparently firmly established, but would be incompatible with the theory that the development of the individual characteristics are fixed ab initio. Although interaction between chromosomes and their environment be brought in, the incompatibility must remain so long as the constitution of the chromosomes is considered to be fixed from the time of fertilisation. It is, then, with something like relief that one encounters the effort of Prof. Dürken to adjust the differences in ideas on the nature of development of the geneticists and of the experimental embryologists. He shows that the results of these last prove the epigenetic nature of development, opposed to the (theoretical) development on a purely chromosomal basis, which, as he maintains, is essentially preformistic in character. The way is open now for readjustment. It is surely reasonable to hold that if any experimental work can throw light on the processes of development, experimental embryology should be able to do so; and this work certainly favours the epigenetic nature of the processes. Thus the rigid chromosomal direction of development is automatically put out of court. On the other hand, genetical theory was introduced for students of heredity, and as a working theory has brilliantly served its purpose. Cytological research has shown that the theory may be nearly true within its own field; but that field is not the general development of the organism. Chromosomes exist in fact, although they do not have continuous existence, and, like all intracellular structures, must undergo epigenetic change. The gene, the lineal descendant of Weismann's determinant and, like it, of more than doubtful material existence, is also subject to epigenetic change, whatever its nature. The conception of this abstract or material gene as the last term in an epigenetic series, expressing itself in the final "characteristic," is one that fits in well. The final philosophic sections of this work, at any rate, give the reader more satisfaction than can be found in the developmental theories based on rigid chromosomal foundations. A word is due to the translators. Like Mundinus, they say that they have not aimed at elegance of style, wishing rather to preserve or reproduce the author's thought without gloss. There is no internal indication of want of elegance, though the English is clear and simple.

THE PROGENY OF SCHIZOPHRENICS

It is common knowledge among psychiatrists that schizophrenics are often childless, but this general impression lacks the support of extensive and accurate statistical analyses. In an attempt to contribute precise information on this point Dr. A. J. Nissen,[1] who is attached to the Norwegian Public Asylum of Rotvoll, has investigated the number of children born to 322 schizophrenics treated at the asylum between July, 1929, and April, 1932. The main facts emerging from this study were the comparative rarity of marriage in this class, the comparative sterility of these few marriages, and the high ratio of illegitimate to legitimate children born to schizophrenics. Altogether only 226 children, legitimate and illegitimate, were born to these 322 patients, who were classified in age-groups to facilitate their comparison with corresponding age-groups in the general population. The census of 1920 provided a not altogether satisfactory control material, as the birth-rate in Norway has declined between this year and 1932. While in the general population in 1920 only 9·43 per cent. of the married women were childless, this was the case with 24·4 per cent. of the 41 married schizophrenic women. Again, in the general population there was an average of 4·02 children every marriage, whereas this average was as low as 2·67 for the married schizophrenics. These figures are, of course, too small to warrant far-reaching conclusions; and there are other sources of error frankly discussed by Dr. Nissen. But with these reservations he has made out an interesting case for the further study of schizophrenia on the same lines. Indirectly such information, thus obtained, may throw light on the part played by heredity in the genesis of schizophrenia.

MELILOT AND MALARIA

For many years it has been popularly supposed in many regions of Africa and Asia that certain species of melilot, a kind of clover, can usefully be grown as a prophylactic against malaria. It will be remembered that Grassi in his closing years raised the important question of the prevalence of anophelines in association with the purity of the water-supply. "Brackish water," he said, "increases the virulence of the malarial parasites." But during his travels in the Argentine he noted that the highly scented blossoms of the scented clover (*Melilotus altissima*) were much frequented by anophelines, which fed upon their juice, and that this plant was not present in malarial districts. The juice of this clover contains a glucoside, coumarin, and he thought it possible that this substance might play a part in the insect comparable to that which quinine plays in man. It will be remembered too that the late Sir William Willcocks tentatively attributed the comparative freedom of Egypt from malaria to the influence of this plant. In 1920 Dr. F. d'Herelle was appointed director of the bacteriological service of the International Quarantine Council of Egypt, and took with him a quantity of seeds of the scented clover known by the Spaniards as "trebol de olor"; but owing to the prevalence of clover in Egypt he was unable to make any extensive experiments with it. Two years ago Stratman-Thomas tried to verify the clover hypothesis in the Mississippi valley. He selected fields where alfalfa had been planted from one to three years, and made an index of the incidence of malaria at various distances from these fields, but he could not find any significant difference, and concluded that the action of clover was nil d'Herelle[1] himself is unable to accept this negative experiment, and considers that observations made in various regions of the world seem to indicate that the primary cause of "anophelism without malaria" is the presence of plants of the genus melilotus, or of some other genus having the same property and containing coumarine in their honey. The outlook for this theory, nevertheless, does not seem to be promising. Those who have worked on malaria in the Delta of Egypt are aware of the existence of endemic foci of the disease in close contact with the clover crops. The explanation of the absence of malaria from the greater part of the Delta appears to lie in the fact that owing to the prevalence of fish in the main canals and the excellent system of drainage, there are no adequate breeding-places or hibernating-places for anopheline mosquitoes of the appropriate species.

B. SUIPESTIFER AS A CAUSE OF DISEASE IN MAN

Bacillus suipestifer, a member of the salmonella group, was first brought into prominence under the name of the hog-cholera bacillus (*Salmonella choleræsuis*, as it is often called in America) as the cause of hog cholera or swine fever. However, while this bacillus is frequently isolated from cases of swine fever, it is now regarded as being not the causal organism but a secondary invader. Much confusion has been caused by a plurality of names, and especially by the use of the term *B. suipestifer* without exact serological definition; but actually this organism is only rarely found to be a cause of human disease. Some continental investigators go so far as to question its pathogenicity to man, while W. G. Savage and P. B. White [1] in 1925 regarded it as an organism of low virulence to man, which can set up an outbreak of food poisoning "only under exceptionally favourable conditions." Further experience, however, showed that it was less rare than had been supposed, and W. M. Scott in 1926 described four separate outbreaks of food-poisoning in this country, in which over 100 cases in all of gastro-enteritis occurred, one being fatal, and in which the bacillus incriminated was *B. suipestifer* (sub-type 2). Savage and White had previously included one outbreak in their series, while at least three outbreaks have been described in U.S.A. These facts seem to establish this organism as a cause, though not a frequent cause, of food-poisoning outbreaks. As usual with the salmonella group, the problem is complicated by further differentiation into sub-types, and there are now three types which have to be considered. One sub-type, generally known as *B. paratyphosus* C, is associated with human disease of the paratyphoid fever type, but, with rare exceptions, is found only in the East, in places such as India, Mesopotamia, and the Balkans. It is separable from, but closely allied to, the two other types. The true suipestifers fall into two sub-types. Sub-type 1, the *American* type, is almost exclusively confined to that continent, and is the type isolated from American swine. It has serological differences and cultural distinctions, such as its failure to blacken lead acetate and its inability to ferment dulcite and arabinose. Sub-type 2 is the Western European type. This is the type which is isolated from swine fever infected swine in this country, and is the one associated with suipestifer food-poisoning outbreaks. This type regularly and rapidly blackens lead acetate and ferments both dulcite and arabinose. That *B. suipestifer* may cause sporadic disease other than food-poisoning in this country has recently been shown by Nabarro and his collaborators,[2] who cultivated this organism from the joints of two children suffering from arthritis. Several isolated cases of paratyphoid fever-like nature due to this bacillus have also been reported in U.S.A.

The story is carried a stage further in a valuable paper by A. G. Kuttner and H. D. Zepp which has just been published.[3] During the winter of 1931–32, within a period of four months, seven children with ages ranging from 7 months to 6 years were admitted to the Harriet-lane Home, Johns Hopkins Hospital, Baltimore. All the cases were entirely unrelated. They were admitted for acute febrile disease of paratyphoid fever type, but showing considerable differences; none was of food-poisoning type. In every child there was definite blood infection, *B. suipestifer* being isolated from the blood. It is of interest that in only one case, in spite of repeated examination, was the organism isolated from the fæces or from the urine. The course of the disease was mild, there were no recurrences or complications, and all the patients recovered after a period of 14 to 29 days in hospital. The bacteriological investigations were carried out with great care. The fact that six of the strains isolated were found to belong to sub-type 2 and one to sub-type 1 is of great interest in view of the known geographical distribution of these three sub-types.

From the different cases recorded we now know that *B. suipestifer* (sub-type 2) can cause disease in man, either in the form of an outbreak of food-poisoning or as illness of the type of paratyphoid fever. It must still be regarded as a rare cause of human illness, but further experience may show a greater prevalence than the reported cases suggest. The sub-type of salmonella found is of importance from the point of view of causation. In the cases of Kuttner and Zepp no sources of infection could be found, but they suggest as most probable infection from specifically infected pork. Since *B. suipestifer* is an organism often associated with swine fever, and undetected cases of this disease may be sold as food, it cannot be excluded as a potential source of infection. The likelihood that it was actually the causal organism in the cases described by Kuttner and Zepp is discounted by the fact that in all but one child the strains were of sub-type 2, whereas the ordinary type in swine in America is sub-type 1. In England this discrepancy does not exist, since all the positive types isolated by White [4] were of sub-type 2, and therefore of the same sub-type as those found in food-poisoning outbreaks. Obviously still more detailed study is necessary before causal factors can be fully established. All that can be said at present is that suipestifer strains from pigs, and probably also from other animals, seem to be of rather low virulence to man, though potential causes of human infection.

THE RESPIRATION OF NORMAL CHILDREN

THE increasing interest taken in the physiology of respiration and its application to clinical problems [5] is illustrated by a recent paper [6] from the University Children's Clinic in Amsterdam. Dr. M. de Bruin, who was investigating with a special type of recording spirometer various problems of basal metabolism in normal children, found that analysis of the curves obtained gave some indication of the normal respiratory functions of the child. In a group of 50 normal children he paid attention to four factors: (1) the rate of respiration over a period of 18 minutes; (2) the depth of respiration, that is the tidal air, from an average of a hundred breaths; (3) the minute volume; and (4) the relationship between respiration and basal metabolism. Great variability was found in the rate of respiration; in 26 boys of ages between 2½ and 10 years the rate varied between 14 and 40 with an average of 23 per minute. The difference on successive days for the same child was only slight, and no reason could be found for producers of the various characteristics. The idea of the chromosomal ordering of the organism from its commencement, however, has not seemed entirely satisfactory. It does not fit in with the facts of wider experience: for example, such phenomena as sex-reversal, regeneration, and the results of experimental transplantation and the like on young embryos were apparently firmly established, but would be incompatible with the theory that the development of the individual characteristics are fixed ab initio. Although interaction between chromosomes and their environment be brought in, the incompatibility must remain so long as the constitution of the chromosomes is considered to be fixed from the time of fertilisation. It is, then, with something like relief that one encounters the effort of Prof. Dürken to adjust the differences in ideas on the nature of development of the geneticists and of the experimental embryologists. He shows that the results of these last prove the epigenetic nature of development, opposed to the (theoretical) development on a purely chromosomal basis, which, as he maintains, is essentially preformistic in character. The way is open now for readjustment. It is surely reasonable to hold that if any experimental work can throw light on the processes of development, experimental embryology should be able to do so; and this work certainly favours the epigenetic nature of the processes. Thus the rigid chromosomal direction of development is automatically put out of court. On the other hand, genetical theory was introduced for students of heredity, and as a working theory has brilliantly served its purpose. Cytological research has shown that the theory may be nearly true within its own field; but that field is not the general development of the organism. Chromosomes exist in fact, although they do not have continuous existence, and, like all intracellular structures, must undergo epigenetic change. The gene, the lineal descendant of Weismann's determinant and, like it, of more than doubtful material existence, is also subject to epigenetic change, whatever its nature. The conception of this abstract or material gene as the last term in an epigenetic series, expressing itself in the final "characteristic," is one that fits in well. The final philosophic sections of this work, at any rate, give the reader more satisfaction than can be found in the developmental theories based on rigid chromosomal foundations. A word is due to the translators. Like Mundinus, they say that they have not aimed at elegance of style, wishing rather to preserve or reproduce the author's thought without gloss. There is no internal indication of want of elegance, though the English is clear and simple.

THE PROGENY OF SCHIZOPHRENICS

It is common knowledge among psychiatrists that schizophrenics are often childless, but this general impression lacks the support of extensive and accurate statistical analyses. In an attempt to contribute precise information on this point Dr. A. J. Nissen,[1] who is attached to the Norwegian Public Asylum of Rotvoll, has investigated the number of children born to 322 schizophrenics treated at the asylum between July, 1929, and April, 1932. The main facts emerging from this study were the comparative rarity of marriage in this class, the comparative sterility of these few marriages, and the high ratio of illegitimate to legitimate children born to schizophrenics. Altogether only 226 children, legitimate and illegitimate, were born to thes 322 patients, who were classified in age-groups to facilitate their comparison with corresponding age-groups in the general population. The census of 1920 provided a not altogether satisfactory control material, as the birth-rate in Norway has declined between this year and 1932. While in the general population in 1920 only 9·43 per cent. of the married women were childless, this was the case with 24·4 per cent. of the 41 married schizophrenic women. Again, in the general population there was an average of 4·02 children every marriage, whereas this average was as low as 2·67 for the married schizophrenics. These figures are, of course, too small to warrant far-reaching conclusions; and there are other sources of error frankly discussed by Dr. Nissen. But with these reservations he has made out an interesting case for the further study of schizophrenia on the same lines. Indirectly such information, thus obtained, may throw light on the part played by heredity in the genesis of schizophrenia.

MELILOT AND MALARIA

For many years it has been popularly supposed in many regions of Africa and Asia that certair species of melilot, a kind of clover, can usefully b grown as a prophylactic against malaria. It wil be remembered that Grassi in his closing years raise the important question of the prevalence of anophe lines in association with the purity of the water supply. "Brackish water," he said, "increases th virulence of the malarial parasites." But durin his travels in the Argentine he noted that the highl scented blossoms of the scented clover (*Melilotu altissima*) were much frequented by anophelines which fed upon their juice, and that this plant wa not present in malarial districts. The juice o this clover contains a glucoside, coumarin, and h thought it possible that this substance might pla a part in the insect comparable to that which quinin plays in man. It will be remembered too tha the late Sir William Willcocks tentatively attribute the comparative freedom of Egypt from malaria t the influence of this plant. In 1920 Dr. F. d'Herell was appointed director of the bacteriological servic of the International Quarantine Council of Egypt and took with him a quantity of seeds of the scente clover known by the Spaniards as "trebol de olor" but owing to the prevalence of clover in Egypt h was unable to make any extensive experiments wit it. Two years ago Stratman-Thomas tried to verif the clover hypothesis in the Mississippi valley. H selected fields where alfalfa had been planted fron one to three years, and made an index of the incidenc of malaria at various distances from these fields, bu he could not find any significant difference, an concluded that the action of clover was ni d'Herelle[1] himself is unable to accept this negativ experiment, and considers that observations mad in various regions of the world seem to indicate tha the primary cause of "anophelism without malaria is the presence of plants of the genus melilotu or of some other genus having the same propert and containing coumarine in their honey. Th outlook for this theory, nevertheless, does not seen to be promising. Those who have worked on malari in the Delta of Egypt are aware of the existence o endemic foci of the disease in close contact with th clover crops. The explanation of the absence o malaria from the greater part of the Delta appear to lie in the fact that owing to the prevalence of fish in the main canals and the excellent system of drainage, there are no adequate breeding-places or hibernating-places for anopheline mosquitoes of the appropriate species.

B. SUIPESTIFER AS A CAUSE OF DISEASE IN MAN

Bacillus suipestifer, a member of the salmonella group, was first brought into prominence under the name of the hog-cholera bacillus (*Salmonella choleræ-suis*, as it is often called in America) as the cause of hog cholera or swine fever. However, while this bacillus is frequently isolated from cases of swine fever, it is now regarded as being not the causal organism but a secondary invader. Much confusion has been caused by a plurality of names, and especially by the use of the term *B. suipestifer* without exact serological definition; but actually this organism is only rarely found to be a cause of human disease. Some continental investigators go so far as to question its pathogenicity to man, while W. G. Savage and P. B. White[1] in 1925 regarded it as an organism of low virulence to man, which can set up an outbreak of food poisoning "only under exceptionally favourable conditions." Further experience, however, showed that it was less rare than had been supposed, and W. M. Scott in 1926 described four separate outbreaks of food-poisoning in this country, in which over 100 cases in all of gastro-enteritis occurred, one being fatal, and in which the bacillus incriminated was *B. suipestifer* (sub-type 2). Savage and White had previously included one outbreak in their series, while at least three outbreaks have been described in U.S.A. These facts seem to establish this organism as a cause, though not a frequent cause, of food-poisoning outbreaks. As usual with the salmonella group, the problem is complicated by further differentiation into sub-types, and there are now three types which have to be considered. One sub-type, generally known as *B. paratyphosus* C, is associated with human disease of the paratyphoid fever type, but, with rare exceptions, is found only in the East, in places such as India, Mesopotamia, and the Balkans. It is separable from, but closely allied to, the two other types. The true suipestifers fall into two sub-types. Sub-type 1, the *American* type, is almost exclusively confined to that continent, and is the type isolated from American swine. It has serological differences and cultural distinctions, such as its failure to blacken lead acetate and its inability to ferment dulcite and arabinose. Sub-type 2 is the Western European type. This is the type which is isolated from swine fever infected swine in this country, and is the one associated with suipestifer food-poisoning outbreaks. This type regularly and rapidly blackens lead acetate and ferments both dulcite and arabinose. That *B. suipestifer* may cause sporadic disease other than food-poisoning in this country has recently been shown by Nabarro and his collaborators,[2] who cultivated this organism from the joints of two children suffering from arthritis. Several isolated cases of paratyphoid fever-like nature due to this bacillus have also been reported in U.S.A.

The story is carried a stage further in a valuable paper by A. G. Kuttner and H. D. Zepp which has just been published.[3] During the winter of 1931–32, within a period of four months, seven children with ages ranging from 7 months to 6 years were admitted to the Harriet-lane Home, Johns Hopkins Hospital, Baltimore. All the cases were entirely unrelated. They were admitted for acute febrile disease of paratyphoid fever type, but showing considerable differences; none was of food-poisoning type. In every child there was definite blood infection, *B. suipestifer* being isolated from the blood. It is of interest that in only one case, in spite of repeated examination, was the organism isolated from the fæces or from the urine. The course of the disease was mild, there were no recurrences or complications, and all the patients recovered after a period of 14 to 29 days in hospital. The bacteriological investigations were carried out with great care. The fact that six of the strains isolated were found to belong to sub-type 2 and one to sub-type 1 is of great interest in view of the known geographical distribution of these three sub-types.

From the different cases recorded we now know that *B. suipestifer* (sub-type 2) can cause disease in man, either in the form of an outbreak of food-poisoning or as illness of the type of paratyphoid fever. It must still be regarded as a rare cause of human illness, but further experience may show a greater prevalence than the reported cases suggest. The sub-type of salmonella found is of importance from the point of view of causation. In the cases of Kuttner and Zepp no sources of infection could be found, but they suggest as most probable infection from specifically infected pork. Since *B. suipestifer* is an organism often associated with swine fever, and undetected cases of this disease may be sold as food, it cannot be excluded as a potential source of infection. The likelihood that it was actually the causal organism in the cases described by Kuttner and Zepp is discounted by the fact that in all but one child the strains were of sub-type 2, whereas the ordinary type in swine in America is sub-type 1. In England this discrepancy does not exist, since all the positive types isolated by White[4] were of sub-type 2, and therefore of the same sub-type as those found in food-poisoning outbreaks. Obviously still more detailed study is necessary before causal factors can be fully established. All that can be said at present is that suipestifer strains from pigs, and probably also from other animals, seem to be of rather low virulence to man, though potential causes of human infection.

THE RESPIRATION OF NORMAL CHILDREN

THE increasing interest taken in the physiology of respiration and its application to clinical problems[5] is illustrated by a recent paper[6] from the University Children's Clinic in Amsterdam. Dr. M. de Bruin, who was investigating with a special type of recording spirometer various problems of basal metabolism in normal children, found that analysis of the curves obtained gave some indication of the normal respiratory functions of the child. In a group of 50 normal children he paid attention to four factors: (1) the rate of respiration over a period of 18 minutes; (2) the depth of respiration, that is the tidal air, from an average of a hundred breaths; (3) the minute volume; and (4) the relationship between respiration and basal metabolism. Great variability was found in the rate of respiration; in 26 boys of ages between 2½ and 10 years the rate varied between 14 and 40 with an average of 23 per minute. The difference on successive days for the same child was only slight, and no reason could be found for producers of the various characteristics. The idea of the chromosomal ordering of the organism from its commencement, however, has not seemed entirely satisfactory. It does not fit in with the facts of wider experience: for example, such phenomena as sex-reversal, regeneration, and the results of experimental transplantation and the like on young embryos were apparently firmly established, but would be incompatible with the theory that the development of the *individual characteristics are fixed ab initio.* Although interaction between chromosomes and their environment be brought in, the incompatibility must remain so long as the constitution of the chromosomes is considered to be fixed from the time of fertilisation. It is, then, with something like relief that one encounters the effort of Prof. Durken to adjust the differences in ideas on the nature of development of the geneticists and of the experimental embryologists. He shows that the results of these last prove the epigenetic nature of development, opposed to the (theoretical) development on a purely chromosomal basis, which, as he maintains, is essentially preformistic in character. The way is open now for readjustment. It is surely reasonable to hold that if any experimental work can throw light on the processes of development, experimental embryology should be able to do so; and this work certainly favours the epigenetic nature of the processes. Thus the rigid chromosomal direction of development is automatically put out of court. On the other hand, genetical theory was introduced for students of heredity, and as a working theory has brilliantly served its purpose. Cytological research has shown that the theory may be nearly true within its own field; but that field is not the general development of the organism. Chromosomes exist in fact, although they do not have continuous existence, and, like all intracellular structures, must undergo epigenetic change. The gene, the lineal descendant of Weismann's determinant and, like it, of more than doubtful material existence, is also subject to epigenetic change, whatever its nature. The conception of this abstract or material gene as the last term in an epigenetic series, expressing itself in the final "characteristic," is one that fits in well. The final philosophic sections of this work, at any rate, give the reader more satisfaction than can be found in the developmental theories based on rigid chromosomal foundations. A word is due to the translators. Like Mundinus, they say that they have not aimed at elegance of style, wishing rather to preserve or reproduce the author's thought without gloss. There is no internal indication of want of elegance, though the English is clear and simple.

THE PROGENY OF SCHIZOPHRENICS

It is common knowledge among psychiatrists that schizophrenics are often childless, but this general impression lacks the support of extensive and accurate statistical analyses. In an attempt to contribute precise information on this point Dr. A. J. Nissen,[1] who is attached to the Norwegian Public Asylum of Rotvoll, has investigated the number of children born to 322 schizophrenics treated at the asylum between July, 1929, and April, 1932. The main facts emerging from this study were the comparative rarity of marriage in this class, the comparative sterility of these few marriages, and the high ratio of illegitimate to legitimate children born to schizophrenics. Altogether only 226 children, legitimate and illegitimate, were born to thes 322 patients, who were classified in age-groups t facilitate their comparison with corresponding age groups in the general population. The census o 1920 provided a not altogether satisfactory contro material, as the birth-rate in Norway has decline between this year and 1932. While in the genera population in 1920 only 9·43 per cent. of the marrie women were childless, this was the case with 24 per cent. of the 41 married schizophrenic women Again, in the general population there was a average of 4·02 children every marriage, wherea this average was as low as 2·67 for the marrie schizophrenics. These figures are, of course, to small to warrant far-reaching conclusions; and ther are other sources of error frankly discussed b Dr. Nissen. But with these reservations he ha made out an interesting case for the further stud of schizophrenia on the same lines. Indirectly suc information, thus obtained, may throw light o the part played by heredity in the genesis o schizophrenia.

MELILOT AND MALARIA

For many years it has been popularly suppose in many regions of Africa and Asia that certai species of melilot, a kind of clover, can usefully b grown as a prophylactic against malaria. It wi be remembered that Grassi in his closing years raise the important question of the prevalence of anoph lines in association with the purity of the wate supply. "Brackish water," he said, "increases th virulence of the malarial parasites." But durin his travels in the Argentine he noted that the highl scented blossoms of the scented clover (*Melilot altissima*) were much frequented by anopheline which fed upon their juice, and that this plant wa not present in malarial districts. The juice this clover contains a glucoside, coumarin, and h thought it possible that this substance might pla a part in the insect comparable to that which quinin plays in man. It will be remembered too th the late Sir William Willcocks tentatively attribute the comparative freedom of Egypt from malaria t the influence of this plant. In 1920 Dr. F. d'Herel was appointed director of the bacteriological servi of the International Quarantine Council of Egyp and took with him a quantity of seeds of the scente clover known by the Spaniards as "trebol de olor" but owing to the prevalence of clover in Egypt h was unable to make any extensive experiments wi it. Two years ago *Stratman-Thomas tried to* veri the clover hypothesis in the Mississippi valley. H selected fields where alfalfa had been planted fro one to three years, and made an index of the inciden of malaria at various distances from these fields, bu he could not find any significant difference, an concluded that the action of clover was ni d'Herelle[1] himself is unable to accept this negati experiment, and considers that observations mad in various regions of the world seem to indicate tha the primary cause of "anophelism without malaria is the presence of plants of the genus melilotu or of some other genus having the same propert and containing coumarine in their honey. Th outlook for this theory, nevertheless, does not see to be promising. Those who have worked on malar in the Delta of Egypt are aware of the existence endemic foci of the disease in close contact with th clover crops. The explanation of the absence malaria from the greater part of the Delta appea pasteurisation, were defeated. It would then have been possible to ask for legislation on the non-controversial questions, but the city council, which approved of the Bill by a large majority, preferred to submit its proposals to a poll of the local electors. The result was disastrous. Anxiety to destroy particular clauses united the forces of the property-owners' association, the ratepayers' association, and the local branch of the National Farmers' Union, and the electors were freely advised that they would be wise to vote against the whole Bill if they objected to any part of it. Although the poll of over 45,000 was unexpectedly heavy, it represented only about 14 per cent. of the total electorate, and because of this general apathy the strenuous and artificially united opposition was able to win the day. Of the 15 clauses one was approved—and it had nothing to do with local government. Yet even the permission to the Royal Infirmary to control certain land and establish clinics and paying wards was granted only by the narrow majority of 1180, and it is reasonable to think that the 21,000 persons who voted against this entirely non-controversial scheme formed a group which was opposing all the items, regardless of their individual merits. It was clear, as the Lord Mayor said afterwards, that reason scarcely entered into the voting, and many people will agree with Alderman G. F. Titt, that the result was "a triumph of organised vested interests against good government."

Dr. Veitch Clark's scheme was an attempt to put in practice a policy—originally outlined, we believe, by Dr. W. G. Savage—that has received full support in our editorial columns.[1] The case for and against pasteurisation of milk has been argued at length in THE LANCET, and during the last few years we have published the reports on which its Manchester opponents chiefly relied. The arguments remain much the same when adapted to the circumstances of this particular locality. At present 75 per cent. of Manchester's milk is pasteurised, 5 per cent. is sterilised, and the remaining 20 per cent. is said to be raw. Prof. H. B. Maitland states[2] that of several hundred samples of unpasteurised milk tested in his laboratory during one year 14 per cent. contained living tubercle bacilli. It is estimated by the public health committee that 40 per cent. of the herds react to the tuberculin test and 2 per cent. of the milch cows have tuberculous udders. While eradication of tubercle from these herds is admitted to be the ideal it is considered impossible at present because of its enormous cost. Meanwhile, according to the chairman of the public health committee, there has been during the last five years an average of 289 cases of non-pulmonary tuberculosis among Manchester children annually, about half of which could be traced to bovine infection. Municipal expenditure, alone, in treating 130 cases for one year is put at £15,000 to £16,000. The answers given to such arguments were many. What is needed, the farmers say, is greater consumption of milk; children prefer it raw, and it is the small retailer of raw milk who keeps the price down. Fresh milk, moreover, is more nutritious, since pasteurisation precipitates calcium and destroys vitamins—a statement which may be read in the light of the Ministry of Health's considered pronouncement that pasteurisation, subject to careful operation and scientific control, "ensures a milk which not only is safe for consumption but also retains its food value practically unimpaired by the heat to which it is subjected." From a letter in the *Manchester Guardian* we learn that "if the Reading results[3] are a criterion of what would happen when everyone was fed on pasteurised milk, the race would soon die out." It was these same results, presumably, that were held to justify distribution of posters and leaflets saying: "Pasteurisation will kill your babies." As propaganda we should prefer the outburst of one of the aldermen, who insisted that people should be able to choose the kind of milk they prefer, and that it is an infringement of the public liberty to be forced to drink such milk as the corporation desires. But, after all, was there really any need for propaganda? As a critic of the farmers and their organisation pointed out, it seems possible that they were once more backing the wrong horse and protesting against their real interests. By opposing the proposals, he said, they appear to enlightened urban opinion as reactionary, which is far from wise at present; the alternative to pasteurisation would probably be a tightening-up of the administration of the Milk and Dairies Order, which would drive many of the smaller men out of milk production; and all this fuss is being made chiefly for the benefit of the producer retailer, who has always been the worst offender in undercutting prices.

If we dismiss the Manchester opposition lightly it is because on the whole the level of that opposition was low. Among the more reasonable criticisms of the scheme was the suggestion that the problem was national and should be treated nationally. But it was one of the merits of Dr. Savage's plan that it avoided the agonies arising from legislation which applies to the whole country, and that it correspondingly lightened inhibitory pressure on the small producer. Compulsory pasteurisation is not a complete and satisfactory solution of the milk problem, and its application anywhere must not be allowed to interfere with attempts to cleanse the milk-supply. At the same time, if rightly used, it offers a partial solution. The time is overripe for an English experiment comparable with the experiment of Toronto, where bovine tuberculosis has been practically abolished; and Manchester, with her record of leadership in public health, is a proper place for this important enterprise. We hope she will think again.

Sir Thomas Horder, who was created baron at the New Year, has taken the title of Lord Horder of Ashford in the county of Southampton.

INDEX TO "THE LANCET," VOL. II., 1932

THE Index and Title-page to Vol. II., 1932, which was completed with the issue of Dec. 31st, is now in preparation. A copy will be sent gratis to subscribers on receipt of a post-card addressed to the Manager of THE LANCET, 7, Adam-street, Adelphi, London, W.C.2. Subscribers who have not already indicated their desire to receive Indexes regularly as published should do so now.

ROYAL NATIONAL ORTHOPÆDIC HOSPITAL.—A Post-graduate course in orthopædic surgery will be held at this hospital, 234, Great Portland-street, London, W.1, and Stanmore, Middlesex, from March 6th to 18th. Full particulars may be had from the hospital.

[1] THE LANCET, 1931, i., 1037.

[2] Reported in Manchester Guardian, Jan. 10th, p. 11.

[3] THE LANCET, 1931, i., 662.

a rate of, say, over 30 in certain circumstances. In the 24 girls of the series the same constancy of rate for the individual child was found, while the rate from child to child varied from 14 to 35 with an average of 23. A similar gross variation from child to child, with a remarkable constancy for the same child, was found in relation to the tidal air. The smallest value found was 174 c.cm., the largest 378 c.cm.; in general the children with the rapid rates had lower tidal air values. One exception showed a high-frequency and big tidal air volume on one day with a lower frequency and small tidal air volume at a later date, but no cause could be found for this. Despite the general finding of inverse variation between tidal air and frequency the minute volumes in the series showed wide variations from eight litres to four litres. Dr. de Bruin suggests as a possible explanation that some of the higher values occur with very shallow breathing, a high minute volume being associated with poor ventilation in the alveoli. This was put forward in a paper from Buenos Aires, recently mentioned in these columns.[7] It is also important in any consideration of minute volume to relate this to the oxygen requirements of the body, as taken alone the ventilation has no absolute value unless body requirements are correlated. Dr. de Bruin consequently compared his estimates of minute volume with basal metabolism findings. The relation, however, was not very close. Of six cases with large minute volumes four showed a basal metabolic rate above the standard, while two were below. In 14 children with low minute volumes seven had raised metabolic rates, six showed lowered values, and one agreed with the standard rates. These findings do not altogether agree with the results of other workers. This may be in part explained by the type of spirometer used and the fact that tidal air was measured as depth of normal inspiration rather than depth of normal expiration. The number of cases investigated was small. Nevertheless Dr. de Bruin's findings are of intrinsic interest and illustrate well the close connexion between physiological and clinical research.

DANGEROUS DRUGS: A MODEL CODE

IN anticipation that the Convention of 1931 dealing with the limitation of the manufacture of dangerous narcotic drugs will be duly ratified and come into force this year, a model code has been drawn up by the Opium Advisory Committee of the League of Nations and circulated. It is hoped that this will expedite ratification and enable the various governments to frame the necessary legislative and administrative measures for application of the new Convention. During the discussion by the Council of the model code, Mr. Wellington Koo, the representative of China, remarked that it was in the matter of dangerous drugs alone that the League of Nations had succeeded in drawing up a model administrative code. He added "that a closer approximation to world uniformity of legislation had been reached in the field of dangerous drugs than in most other fields of international activity." M. de Madariaga, representing Spain, recalled that League experience in regard to narcotic drugs proved that the real source of the evil was the manufacture rather than the traffic, and suggested that this experience might usefully be communicated to the disarmament conference, where control of manufacture was no less important than control of traffic. The draft model code contain suggestions as to the connotation of "narcotic drugs," "reserve stocks," and "government stocks," and deals with methods for determining the annual estimates to be furnished by each government which form the basis of the plan for limitation of manufacture. It has made clear from the official statistics available that the stocks in existence at the end of 1931 were sufficient to meet all the scientific and medical needs for at least a year. As regards illicit traffic, it is interesting to note that in 1931 the United States of America were the chief victims of such traffic. The quantities there seized in that year were of raw opium 1389 kg., of morphine 258 kg., of heroin 238 kg., and of cocaine 5 kg. The Council of the League meets on Jan. 23rd, when it is hoped that progress may be reported as regards ratification of the Limitation Convention; and the Central Opium Board will hold its next meeting at Geneva on Jan. 25th.

CARBON MONOXIDE POISONING AND MOTOR ACCIDENTS

ON another page Dr. J. S. Owens writes on the risk of carbon monoxide poisoning which arises from the general use of motor-cars. It is, as he says, hard to be sure what damage may be done to people exposed to exhaust gas in small doses over long periods, and in France the statement has lately been made that drivers of public service vehicles suffer a degree of chronic poisoning which increases their liability to accidents. Cazeneuve, Tanon, and Neveu,[1] who have already written on the subject in the hope of ensuring that the examination of drivers in the provinces shall be carried out in accordance with the law, have made 4000 examinations and say that one driver out of every four shows unequal dilatation of the pupils. They have carefully eliminated any possibility of syphilis, and ascribe the symptom to an intoxication of the grey matter of the medulla. Testing 15 of their friends, they found that ten showed inequality after driving a closed car with all the windows shut; mydriasis, as in the public service drivers, was always on the left, and return to normal took place after intervals varying from one to eight hours. Inhalation of petrol fumes produced similar effects in certain subjects. In three cases of accident where the driver had complained of faintness just before the collision, they found obvious leakage of exhaust gas through the floor boards, and consider that many mishaps must be due to this cause. They think that certain drivers are more sensitive than others, and that alcohol or over-eating predisposes to this form of intoxication.

MANCHESTER AND PASTEURISATION

MANCHESTER has temporarily lost her reputation for sound sense. About a year ago the public health committee approved the proposal of Dr. R. Veitch Clark, the medical officer of health, that the city should take powers to insist that all milk—other than Certified and Grade A (tuberculin-tested)—sold within its borders should in future be pasteurised. This proposal was rightly accepted by the city council and was embodied in one of fifteen clauses in a new Corporation Bill. The Bill, before going to Parliament, had to be submitted to a town's meeting, and the opposition to some of its provisions was so well organised that five of the clauses, including compulsory cent. of carbon monoxide in the exhaust gases, and this makes them a very deadly poison unless rapidly diluted.

---

[7] THE LANCET, 1932, ii., 1345.

[1] Bull. de l'Acad. de Méd., 1932, cviii., 1624.

We have had some experience in England also in vehicular tunnel ventilation, and an investigation into the ventilation of the Blackwall and Rotherhithe tunnels has been made by Mr. C. J. Regan, and published in the L.C.C. Annual Report for 1930 (Part III., p. 271). In these tunnels the maximum permissible concentration of carbon monoxide was fixed at 2 parts in 10,000.

CARBON MONOXIDE IN CITY STREETS

It is found that the air in busy city streets contains a measurable quantity of CO, averaging 0·8 parts per 10,000 in 14 towns of the U.S.A., about 0·5 in the street air in Chicago, and ranging from this to about 0·15 in suburban districts. Samples taken by Mr. Regan in central London, during the winter, gave 0·3 parts per 10,000. The concentration in the open street thus rarely approaches the danger limit, but it must not be forgotten that although a dangerous concentration may be rare, it does not follow that it never occurs.

In all cases of atmospheric pollution we have been accustomed to rely upon the scavenging action of the wind to clear away the impurities. This is the case with the smoke from our chimneys, grit and fumes from factories, as well as the fumes and poisonous gases permitted to escape from the exhausts of motor vehicles. Now it is true that there is usually some wind to carry these away; also that a concentration of vehicles at any particular place may not occur at the moment when the wind has failed. Again, we have the possibility of abnormalities in the vertical temperature gradient preventing the upward escape of fumes, but what we perhaps do not realise is that all the conditions favouring high concentration may some time occur together.

For example, a long street of high buildings may be crowded with motor vehicles owing to some hold-up of the traffic. This may happen on a day when the wind has fallen and when the temperature gradient overhead does not encourage the upward escape of hot gases. In such circumstances it appears possible that the concentration of poisonous gases might become sufficiently high to be dangerous. It was coincidence of certain conditions which brought about the accident in the Liberty tunnels.

The affinity of hæmoglobin for carbon monoxide is 300 times as great as for oxygen. Hence, in the presence of any particular concentration, the CO will be seized in preference to the oxygen, and the effect will be to produce a condition of the blood in which a definite saturation value of CO will be reached. It would seem, therefore, that however long the exposure to air containing carbon monoxide, the degree of saturation of the blood can never exceed a certain value corresponding to the concentration in the air. This does not, however, preclude the possibility that low concentrations of CO may be injurious when breathed for long periods.

Reference has been made to the use of heavy oil engines such as Diesel engines, and although these have not yet come into general use, there is a general tendency in that direction, and it is interesting to note that the exhaust from such heavy oil engines usually contains a very small proportion of carbon monoxide under normal running conditions, certainly much lower than that produced from petrol engines.

THE EGYPTIAN LUNACY REPORT[1]

THE Lunacy Division Report for the year 1931, made to the Egyptian Ministry of the Interior and issued from the Public Health Department, reaches us a year later than the events which it chronicles. The report differs in certain respects—one, in particular, to which detailed attention must be drawn—from the reports previously issued. It is very brief, and brevity is no disadvantage unless it is obtained by the omission of matter pertaining to the subject. But it is a little surprising that the information from an important organisation, responsible for the treatment of 5262 cases in the year, and dealing with a resident insane population of 3227, should be considered to be adequately afforded in five and a half pages of text, consisting mostly of tabular statements. The shortness of the report has led to exclusion of the information formerly furnished as to the cost of new additional buildings and their maintenance; as to the number of seriously injured persons admitted; and as to the forms of insanity of the insane criminal patients; the religions and races of the admissions; their monthly distribution and occupations; the nationalities of the general paralytics, and the distribution of the pellagrins. No details of autopsies, or of the nature of the 17 accidents recorded are given.

It is stated that the death-rate calculated on the total number treated has risen from 5·5 in 1928 to 7·1 in 1931, a rise of 29 per cent. The value of the explanation suggested for this increase—viz., the feeble physical condition of some of the admissions—is discounted by the fact that the classification of admissions into "good," "poor," and "very bad," depends a good deal on the personal equation of the reporter, and this may vary with changing observers. The high death-rate among the chronic cases suggests defects in the nutritional value of the food, or some general factor which could affect all the inmates. A comparison of the death statistics of the year 1928 with those of 1931 shows that deaths from pulmonary diseases and tuberculosis rose from 40 in 1928 to 73 in 1931; from general paralysis, from 11 to 38; from pellagra, from 43 to 66; from senile decay, from 12 to 28; from kidney disease, from 18 to 40; from epilepsy, from 6 to 20 In all, these six categories account for an increase of 135 deaths The significance of some of these rises seem to deserve study. In comparing the death-rate of 1931 with that of previous years, the number of deaths of addicts should have been stated, and their figure deducted from the total number of deaths; a corresponding deduction should, of course, have been made from the total number under treatment; the death-rate of the insane, calculated on these reduced figures, would then have been comparable with that of previous years.

The reduction in the number of pellagrins admitted is worthy of note, the number having fallen from 189 in 1923 to 53 in 1931, a figure actually less than the number of deaths from pellagra during the year 1931 (66). It would be of great interest to know whether there has been noticed a corresponding diminution in the prevalence of pellagra in Egypt generally. If so, can the reason be found in any change in the diet of the fellaheen, perhaps in an increased consumption of wheat instead of maize?

The most outstanding event of the year, in the

SPECIAL ARTICLES

CARBON MONOXIDE POISONING FROM MOTOR-CAR FUMES *

By J. S. Owens, M.D. Dub., A.M.Inst.C.E., M.I.Mech.E.

SUPERINTENDENT OF OBSERVATIONS ON ATMOSPHERIC POLLUTION, DEPARTMENT OF SCIENTIFIC AND INDUSTRIAL RESEARCH

Public attention for some time past has been directed towards the danger of poisoning from the carbon monoxide fumes emitted in motor-car exhaust gases. It is well known that carbon monoxide is an extremely poisonous gas, but there is still some difference of opinion as to whether a chronic form of carbon monoxide poisoning may not exist which has not yet been recognised as such.

Tables of permissible concentration of CO in air are available based on different authorities. For example, the following is from Yandell Henderson and H. W. Haggard [1] :—

Concentration.	Carbon monoxide per cent.
Allowable for an exposure of several hours ..	0·01
Can be inhaled for one hour without appreciable effect..	0·04–0·05
Causing a just appreciable effect after one hour's exposure	0·06–0·07
Causing unpleasant but not dangerous symptoms after one hour's exposure ..	0·1 –0·12
Dangerous for exposure of one hour	0·15–0·20
Fatal in exposure of less than one hour ..	0·4 and above.

Another method of approach, for which Prof. Henderson is responsible, takes into account the time of exposure as well as the other factors. He has evolved the following method of estimating the effects of CO concentration :—

If x is the number of units of CO per 10,000 of air,
t is the number of hours exposure,
c is a factor which is 1 for a man at rest and 2 for a pedestrian—
then if the product
ctx lies between 0 and 3, no ill effects are felt.
approaches 6, slight ill effects are felt.
" 9, headaches are produced.
" 15, danger to life is incurred.

It is probably true that smaller concentrations than those mentioned, if breathed for a sufficiently long period, would be injurious, and it is quite probable that many of the headaches from which people in closed cars suffer are due to the leakage of exhaust fumes to the inside of the car.

ROAD TUNNELS AND GARAGES

Attention was first prominently drawn to the danger from exhaust fumes by an accident which occurred on May 10th, 1924, in the Liberty tunnel, Pittsburgh.[2] This is a tunnel 5889 ft. long, consisting of two tubes, 26 ft. wide at the floor and 20 ft. high, both lined with concrete, and straight. When the tunnels were constructed they were operated for about seven months without mechanical ventilation. Then an accident occurred which held up the vehicles in the tunnel, the CO concentration rapidly increased up to 25 parts in 10,000, and a number of people were partially asphyxiated. Shortly after this steps were taken to install mechanical ventilation of the "transverse" type, in which the inlet for fresh air is in a duct along the floor with lateral openings, while the exhaust is by a duct along the roof with similar lateral openings. This transverse method removes the impurity from a particular point of the tunnel without having to draw it along over any considerable length of tunnel as would be the case if it were ventilated from the end.

It was found that the average amount of carbon monoxide produced per minute per motor vehicle in this tunnel was about half a cubic foot, and it was concluded that an average pollution of 3 parts, with a maximum of 6 parts per 10,000, should not be exceeded. The transverse method of ventilation was fully developed for other American tunnels, and has been applied in the Holland vehicular tunnel under the Hudson. Here a standard of 4 parts per 10,000 was at first allowed, but it was subsequently reduced to 2½ parts per 10,000 for a period of five minutes. It is stated, in a paper [3] describing this tunnel, that experiments made on city streets showed a concentration in the open street up to 1·7 parts per 10,000 on still days.

The poisonous nature of the gases which collect in closed garages is now well known, and a number of people have lost their lives through remaining in closed garages with their car engines running. Experiments have been made in Washington at a large Government garage which showed that there was an average concentration of CO of 1 part per 10,000, rising sometimes to 8·9 parts. At another garage the average for a day was 1·64 parts per 10,000, and for an hour 4·33.[4]

COMPOSITION OF EXHAUST GASES

In motor vehicles the fuel burnt is petrol or benzol, and these are composed practically entirely of carbon and hydrogen, with a negligible percentage of sulphur amounting to about 0·02 per cent. for petrol and 0·3 per cent. for benzol. Neglecting the sulphur, either petrol or benzol should burn to carbon dioxide and water, but in fact it is found that is not the case, and perfect combustion only occurs when the conditions are exactly right and the air-supply just correct in quantity. For example, with a little over 15 lb. of air supplied per lb. of petrol, the exhaust gases should contain nothing but CO_2, water, and nitrogen, but if the air-supply is reduced it is found that the percentage of carbon monoxide rises very rapidly.

Table showing Composition of Exhaust Gases
(A. W. Judge [5])

Ratio of air to petrol by weight.	Per cent. composition.						Percentage of heat of fuel used.
	CO_2	O	CO	H	CH_4	N	
9	6·7	0	12	4·3	1·4	75·6	58
10	8·2	0	9·6	3·5	1·2	77·5	61
11	9·6	0	7·3	2·6	0·9	79·6	71
12	11·1	0	5·0	1·8	0·6	81·5	79
13	12·5	0	2·6	0·9	0·3	82·7	89
14	13·5	0·4	0·4	0·1	0	85·6	99

The accompanying Table shows the way in which the exhaust gases vary in composition as the air supply is varied.

We may take it that there is usually about 5 per misapprehension for which the doctor was in no way responsible, the information given was not the information required. The court therefore made a further adjournment in order that the doctor might give additional information whereby the credibility of a witness in the case might be tested.

Medical practitioners in charge of clinics may have occasion to emphasise the assurance of professional secrecy in order to persuade patients to present themselves for treatment with confidence, and to continue the treatment for the necessary period. In these circumstances, the practitioner will naturally deprecate and resent being placed in the witness-box and asked to disclose the facts of treatment. It looks like a breach of faith towards the patients in general, many of whom may know that he has given such evidence, but may not know that he gave it at the express request of a patient. Legally, the Burslem magistrate's view was undoubtedly correct. The privilege of secrecy belongs to the patient; the patient can waive it. The Burslem case differed only in degree from the ordinary occasions when a patient asks his medical attendant to give evidence of his injuries in support of a claim for workmen's compensation or for damages against a negligent motorist. Patients would be at a serious disadvantage if they could not claim this aid. The privilege of professional secrecy between solicitor and client is far more firmly established than that between doctor and patient. A solicitor is never compelled by a court to disclose his client's confidences. Yet he often goes into the witness-box to state facts in his client's favour.

Inquest on Christian Scientist

A recent inquest on a Christian Scientist at West Norwood was on familiar lines. Medical evidence showed that the patient had advanced heart disease of long standing and was almost gasping for breath; she would still be alive if a doctor had been called in in good time. A Christian Science practitioner explained his method of treatment, and was asked the usual question as to how he would treat a broken leg. He said he had practised for 20 years; he took fees, and he professed to cure all ailments. The husband of the deceased explained her objection to the calling in of a medical practitioner. The jury added a strong rider condemning the denial of the benefit of modern medical science.

These cases have little medico-legal interest. Parliament has recognised Christian Science treatment by saving words in the Nursing Homes Registration Act; it is impossible therefore to suggest that the treatment and its consequences are illegal. The law stops far short of applying the principles relating to "suicide pacts" to cases where husband and wife agree to follow the rules of Christian Science.

SCOTLAND

(FROM OUR OWN CORRESPONDENT)

PSYCHIATRY IN EDINBURGH

Dr. D. K. Henderson, who succeeds Prof. George Robertson in the chair of psychiatry as well as at the Royal Mental Hospital, gave his inaugural address on Jan. 12th. The chair owes its establishment largely to the late Sir Thomas Clouston and the late Prof. Robertson, who made psychiatry a reality in the University and in the Jordanburn Clinical Laboratory. Edinburgh is now peculiarly well-equipped over the whole field of mental diseases and mental deficiency. The superintendent of Bangour Mental Hospital, which is now under the municipality, is also the superintendent of Gogarburn institution, which has been designed for the early medical and hospital treatment of the insanities as well as for the care of the feeble-minded. He is, further, head of the service for the management of mental defectives in the special schools of the city, under the medical officer of health.

Prof. Henderson thus comes to the University, or rather back to it, to find a well-organised system for dealing with mental disorders in all their phases. In his lecture he showed a comprehensive grasp both of concrete detail and of broad principles, and also a sympathy with all varieties of treatment when kept in their proper place and perspective. One had to remember, he said, the many popular lines of interest for those "who faltered by the wayside and who still found their satisfaction and help in simpler beliefs." The influence of the mind in therapeutics was as powerful to-day as in the past centuries. The work of the psychiatrist concerned itself with the primal instinctive, impulsive, emotional needs of our being, with the instinct of flight and the emotion of fear and rage, with repulsion and disgust, with interest and wonder, with self-abasement, and self-assertion, with instinct of reproduction, the herd instinct, and with everything that determined the type of people we were. "That was too big an affair to be left to chance and the pious hope that everything would work out for the best in this best of all possible worlds."

"Here, in the present," he said, "we must build a psychiatric organisation, so that persons suffering from nervous and mental illness might obtain skilled help at a time when they were susceptible of betterment. The enthusiasm and initiative of his predecessor, Prof. Robertson, provided such an organisation for Edinburgh, and it would be his endeavour to keep the machinery in good working order."

THE ROWETT INSTITUTE

Through the generosity of Lord Strathcona and other friends, the Rowett Institute, at Aberdeen, has been presented with "Strathcona House," for the accommodation of research workers, who from time to time come from all parts of the Empire. The new hostel contains a large dining hall panelled in oak, a common-room in oak, and 15 bed-sitting rooms, in addition to kitchen and other essentials. Lord Strathcona presided at an inaugural dinner. The meeting included representatives from leading Government departments, research institutes, and, generally, from those concerned in the problems of animal and human nutrition. Sir Godfrey Collins, Secretary of State for Scotland, said that the influence of the institute had reached to all parts of the British Commonwealth. Sir William Hardy, F.R.S., Mr. F. L. McDougall, Sir Walter Fletcher, F.R.S., and Major Walter Elliot, Minister of Agriculture, also took part. The director of the institute is Dr. John Orr, F.R.S.

PARIS

(FROM OUR OWN CORRESPONDENT)

MORE DISCIPLINE WITHIN THE MEDICAL PROFESSION

It is more or less a coincidence that both France and Belgium are at present trying to put their houses in order in the matter of medical discipline. Neither country has hitherto enjoyed the alleged benefits conferred on the doctors in England by the General Medical Council. Of course there has all the time been opinion of the Director of Lunacy, is that the Khanka Mental Hospital has been so divided that one portion forms a criminal asylum for men, and one for ordinary cases of lunacy, a decision being made at the mental hospital of Abbâssîya as to the mental state of criminals. To find room for all these cases at Khanka must be difficult, but in the following paragraph of the report we find that "it was decided to admit drug addicts on their own personal request, even to the extent of overcrowding the hospitals," and that "Khanka should take all the non-paying cases." This we think to be a far more outstanding event. It was emphasised in the report for 1930 that the mental hospitals were, already overcrowded to the extent of 344 patients, on an average, beyond the number of beds existing; while 1113 patients had been discharged still insane during that year owing to lack of room It was further stated in that report that this discharge of the insane was "a very disturbing proposition." The disturbance must be aggravated if a decision is taken in the following year to admit a large number of persons not certified to be insane, but merely the subjects of vicious habits. Cases of real insanity from drugs continued, of course, to be certified and properly admitted, to the number of 52; but nearly 500 persons of vicious drug habits were admitted, while, consequently, an equivalent number of insane persons must have been denied the treatment which they would otherwise have had, and for which the hospitals were instituted.

No information is given as to the nature of the drugs used by these addicts, whether it was hasheesh, cocaine, morphia, heroin, or some combination of them. But the nature of the procedure will be better realised if we can imagine 20,000 habitual drunkards being admitted as voluntary patients into the already full county and borough mental hospitals of England in a year, and an equal number of insane patients discharged to make room for them. The admission of these addicts to the necessary exclusion of the insane who require hospital treatment is a retrograde measure, and appears also to be a fiasco, for the report states: "It is regretted that the experiment in so far as curing addiction is concerned is a failure, the effects of over-indulgence in drugs can be cured easily, but the cause of the addiction remains uncured, except in the extremely small class of accidental addiction. Drug addiction depends on the moral sense and strength of will of the individual, and cannot be improved in a few months, much less in the time taken to cure the ill-effects of the overdosing. It is feared that the only radical cure for addiction is to improve the moral sense of the individual. In the meantime, the only hope is to make access to drugs very difficult, and their possession as unpleasant as possible." It would be of interest to know where the responsibility lies for the decision to admit drug addicts into the mental hospitals, for the lunacy authorities could hardly have welcomed the proposal. The admission of these addicts into the ordinary hospitals of the Public Health Department, or into special isolation camps would have been reasonable, or into prison infirmaries, when the individuals could have been charged with trafficking in prohibited drugs; but why send them to institutions already notoriously crowded, and intended for quite a different class of cases?

A study of the figures suggests that the intermingling of drug addicts with the insane has produced confusion in the figures recorded, as indeed it may well have done in the hospitals themselves. Thus the 492 addicts appear in some tables but, quite unaccountably, not in others—e.g., they swell the admission figure in Table I. to an unprecedented height (2225), and the number of recoveries has risen from 119 in 1930 to 490 in 1931. This reckoning of addict discharges as recoveries renders the figures shown valueless as an indication of the recovery rate among the Egyptian insane. In Table V. the inclusion of the addicts increases by 492 the figure credited to one of the causes of insanity in that table—viz., drugs. This table already (and rightly) included 52 cases of real insanity due to drugs. Yet in Table III. (Forms of Insanity) and Table IV. (Distribution of Admissions in the Country) the 492 addicts do not figure, being now apparently considered not to be suffering from insanity. This apparently arbitrary use of the figures relating to addicts wants explanation. If they appear in one table why not in all? In Table III., which professes to show the form of insanity of each person admitted, the total number of persons is given as 1556—i.e., the 2048 persons mentioned in Table I. less the 492 addicts; but, according to Table I., 80 or nearly 80 of these 1556 persons were not insane, and should have been so entered in Table III., while only the balance of 1476 persons should figure in Table III. under the ten forms of insanity mentioned in it. These 80 sane persons also figure in Table V., and the causes of their insanity (or sanity?) are professed to be given; perhaps chiefly among the 77 cases of unknown causation. These 80 sane persons also appear inappropriately in Table IV. Of course, they should not have appeared in any of these three tables.

It would have been wiser to have kept the statistics as to drug addicts completely separate from those relating to the ordinary insane. But, in view of the failure of the experiment in their admission to the mental hospitals, it is to be hoped that the procedure will be discontinued. The local lunacy authorities could make strong representations on the subject, and in so doing could rest assured that their fellow-workers in British mental hospitals would sympathise with their efforts to change an unfortunate policy.

The reduction of the report to its present size renders it difficult to form an adequate picture of the progress of lunacy work in Egypt, a matter of real regret. It is to be hoped that the lunacy authorities in Egypt will persuade the Government to remove any restraint that may have been exercised out of misplaced economy.

MEDICINE AND THE LAW

Patient Waives Professional Secrecy

THE stipendiary magistrate on Jan. 10th resumed the hearing at Burslem of the affiliation proceedings in which a doctor declined to give evidence at the request of a patient. The defendant denied paternity, said the girl's story was untrue, and called the doctor (who had treated him at a clinic under the Stoke-on-Trent public health department) in support of his statement. The doctor based his refusal on grounds of public policy. The magistrate, in adjourning the case in order to give the doctor a chance of considering the position, pointed out that the privilege of secrecy was not vested in the doctor but in the patient. A patient who wished his doctor to disclose something was entitled to have the benefit of the doctor's evidence. On resumption of the proceedings, the magistrate said the doctor had now supplied certain information in writing. It happened that, by a e was always ready and willing to give treatment nd to issue certificates when asked by a patient o do so. The insurance committee's representative ought to argue that Dr. Z had failed to comply with he terms of service even though he had not committed breach of the terms. The report on the appeal ejects this subtle distinction. It agrees with Dr. Z hat his obligation to give treatment does not begin ill the patient asks for it; it holds that there has een no breach of the terms of service. The report, however, does not overlook the omission to give certificates in the prescribed form. It observes that it seems to have been suggested that it did not matter whether the certificates tendered by insured persons to an approved society were in the proper form or not, or whether they did or did not contain the required information. It recalls the fact that the forms are the outcome of consultation and agreement and that they have been accepted by insurance practitioners generally, from 1914 onwards, as conveying information which it is important for the societies to have and not unreasonable for panel doctors to give. Although societies do in fact accept certificates not on official forms, the report regards the arrangement at this hospital as placing the insured persons on Dr. Z's list in an unfortunate position. Such an arrangement, "though not necessarily inconsistent with the requirements of the terms of service, obviously does not conform to that spirit of reasonable coöperation between insurance practitioners and approved societies which we are glad to think generally prevails." The Minister has allowed Dr. Z's appeal; he directs that no order be made as to costs.

A Compassionate Arrangement

The Minister has allowed another practitioner's appeal in a case turning upon the extent to which a panel doctor may delegate work to an assistant. A doctor carrying on panel practice in south-east London died in 1928 leaving several young children. The two eldest were studying medicine but, not being yet qualified, were not available to succeed to their father's practice. By a compassionate arrangement designed to bridge the interval which must elapse before the children became qualified, an elderly practitioner, a friend of the family, undertook the practice himself. He changed his surname by deed poll to that of the deceased; he joined the London panel list, and put up his plate at the deceased's surgery. In 1929 he asked the London insurance committee's permission to employ an assistant. Leave was granted for 12 months on the applicant's assurance that he meant to attend the surgery daily himself, mornings and evenings. In 1930 the decision was reviewed. It was found that the assistant had signed every prescription for an insured person during the previous year. There was a question of the panel practitioner's fitness, but the panel committee declared him to be mentally and physically fit for his work in spite of his 80 years. From this point he did sign some of the panel prescriptions, but the large majority were still signed by the assistant. In 1932 the insurance committee took up afresh the question of withdrawing consent to the assistant's employment. The panel committee was of opinion that the practice and the insured person's interests had not suffered and that it would be unreasonable to withhold consent; the assistant did not want to become a partner; if he could not be employed the practice would suffer because a fresh practitioner would have to be brought in. The insurance committee nevertheless withdrew consent and the panel doctor thereupon appealed to the Minister. Among the witnesses at the hearing was Dr. Batteson, chairman of the London panel. He thought this was not a case of farming-out; there were no branch surgeries; one doctor was not exploiting another, and there was no prejudice to the interests of other practitioners; the appellant seemed to exercise a reasonable supervision. The persons appointed by the Minister to hear the appeal accepted and confirmed this evidence. There was proper continuity of treatment and there was no failure to comply with requests for personal attendance. If the insurance committee had refused permission after experience of the first 12 months of the arrangement, their decision could hardly have been held unreasonable. But now the position was admittedly better; the practice was satisfactorily conducted; the appellant himself was apparently taking a slightly more active part; and the deceased doctor's two children were on the point of being qualified. It was true that the insurance system must be embarrassed if all the treatment is given by a practitioner who is not the person in direct contractual relation with the insurance committee and responsible for mistakes which occur. But it was not possible to define exactly the extent to which a principal must personally participate in a practice. The Minister allowed the appeal but made no order as to costs. In this and the previous successful appeal, the London and Counties Medical Protection Society conducted the appellant's case.

Publicity and Prejudice

Cases have occurred in various parts of the country in which, either through local gossip or publicity of the facts locally in a sparsely medically populated area, it has been easy to indentify the doctor if not the complainant (through the veneer of Dr. A or Mrs. R) in the report of a medical service subcommittee to the insurance committee. The same applies to the parties to a pharmaceutical service case. The members of the main committee, on the other hand, do not know the names of the individuals concerned when they discuss the report and its suggested recommendations. An insurance committee has no power to alter the findings of fact set out in these service reports, but it can amend the recommendations based on the findings, alter a caution to a censure, increase the sum of money suggested to be withheld, or decide to ask the Ministry to hold an inquiry as to whether the continuance of Dr. A on the panel is prejudicial to the efficiency of the service. The insurance committee thus has serious powers over and above those of its statutory subcommittee, and it is on this account the more important that its members should read the reports and agenda papers with an open mind before coming to a decision. And herein lies the difficulty, for agenda papers of the insurance committee may be circulated to the press before they reach the Ministry of Health, and it has happened on more than one occasion that some paragraph prejudicial to one of the parties concerned in the case—probably the doctor—has appeared in a local paper of an area in which the doctor is well known and recognisable by the facts stated.

In such conditions it is not likely that justice will be done, and the Ministry of Health, after consulting with the Insurance Acts Committee, has circulated a letter to insurance committees in which the opinion is expressed that no publicity should be given to any report of a service subcommittee before the

the law of the land from the impartial constraint of which the medical profession has enjoyed no special immunity. For example, the French doctor who omits to take the necessary measures in a case of notifiable disease, and whose omission has certain deplorable consequences, may find himself suffering certain legal penalties. If his excursions in the operative field lead to disaster for the patient, they may ultimately lead to disaster for the surgeon himself in the law courts. But for a long time there has been a growing feeling in both countries that the sins of omission and commission in the practice of medicine are so specialised that none but doctors themselves possess the necessary knowledge for dealing with them. We set a thief to catch a thief, and the ex-poacher is the best gamekeeper; though far be it from me to suggest that the knowledge your General Medical Council brings to bear on disciplinary cases has been acquired by any personal experience. In Belgium there has been some opposition on the part of the medical profession to the principle of a medical court or council. But when, last December, a Bill embodying this principle was put before the French Chamber of Deputies, it was passed without discussion. This Bill provides for a Medical Corporation or Order, which, though in a sense autonomous, is to be a State-sanctioned body. In every department there is to be a separate Order, each with its own president and council. Every doctor who is not in the army, navy, or air force must join one of these Orders, and he cannot belong to more than one. Presumably there will be some sort of central body coördinating the activities of all the Departmental Orders. Their functions are to be manifold, from administering benevolent funds to investigating and dealing with cases of alleged infamous conduct in a professional respect. The French legal profession has already had a considerable experience of the disciplinary workings of a similar body, the constitution of which has, to a certain extent, been a model for the framing of the new medical Order.

PYREXIAL THERAPY IN EXPERIMENTAL SYPHILIS

C. Richet and J. Dublineau have reported to the Academy of Medicine on some experiments with syphilitic rabbits submitted to a high temperature alone or in conjunction with some chemotherapeutic drug. By artificially raising the temperature of a rabbit for 22 minutes to 41·4° C., or for 15 to 17 minutes to 42·4° C., they succeeded in curing the syphilis in three cases, while they failed in two other cases. They ascertained whether a given rabbit was cured or not by injecting some of its tissues into a series of healthy rabbits and noting the results. In four cases the temperature of syphilitic rabbits was artificially raised at the same time that an infra-curative dose of arsenic was given. In every case the syphilis was cured. Investigations in vitro also showed that a temperature of 41° C. maintained for 30 minutes or longer robbed the treponema of all its virulence, though limited movements might continue two hours longer. It should be noted that Levaditi and many others have also contributed to the study of thermotherapy in experimental syphilis.

TREATMENT OF CANCER OF THE CERVIX

At a recent meeting of the Société Nationale de Chirurgie, Prof. Jean-Louis Faure weighed the claims of operative treatment against those of radium treatment in cancer of the cervix, and cited statistics in favour of the former. Among the last 200 cases of cancer of the cervix observed in his hospital, there were 171 pavement-celled cancers and 29 cylindrical-celled cancers—i.e., 14·5 per cent. of the latter. Now, according to Prof. Regaud, this latter class is radium-resistant. If his opinion is correct—and it is not unequivocally confirmed by the observations of Gosset and Wallon—then some 15 per cent. of all cases must be considered as hopeless if operative interference is abandoned. Another objection to radium treatment is its immediate mortality which, according to various statistics, ranges from 2 to 7 per cent. As for the late effects of radium treatment, the recent researches of Proust, published last October, are most disquieting. In 1926 he was able to show that 40 per cent. of his patients treated by radium could be considered as cured after an observation period of one to four years. But in 1932 only 10 per cent. still survived. The actual number of patients treated in the period 1922–1925, inclusive, was 236, and the survivors in 1932 numbered only 24. Prof. Faure remarked incidentally that in judging of the durability of the results achieved by the two methods of treatment, a longer observation period must be required of radium than of operative treatment. The patient who has been operated on and has remained symptom-free for two years, has nine chances out of ten of being permanently cured. But it may be necessary to wait five or even ten years before the permanency of a radium cure can be claimed. For the inoperable case radium may be admirable, but for the operable case it is, in his opinion, inferior to operative treatment.

PANEL AND CONTRACT PRACTICE

Treatment of Hospital Staffs

A RECENT appeal concerned the arrangements for medical treatment of hospital staffs. It has been customary in a certain hospital in London for the senior assistant medical officer to attend to the medical requirements of the staff. Dr. A, who held this appointment, refused from the beginning to undertake national health insurance work, mainly, it seems, because of his conscientious objection to issue certificates disclosing particulars of his patients' ailments. In 1913 Dr. Z, the medical superintendent of the hospital, joined the medical list; a large number of the insured members of the staff placed themselves on Dr. Z's list; the capitation fees which Dr. Z receives he places to a fund for the benefit of the staff. The insured members do not usually apply to Dr. Z for treatment; they are treated by Dr. A. In fact Dr. A does Dr. Z's work, but Dr. Z makes no personal profit from the arrangement. Dr. A, however, declines to issue certificates in the prescribed form required by approved societies; his certificates merely state that the insured person is "off duty owing to ill-health." This economy of information seems to have caused remarkably little administrative difficulty; the absence of the proper certificate has not prevented the insured persons from obtaining sickness benefit. But in one specific case an approved society complained to the Ministry that they "tried to obtain a proper certificate but the doctor who signs it objects to giving any other." The London insurance committee decided that Dr. Z had failed to comply with the terms of service. On appeal he argued that his duties under the medical benefit regulations do not arise until patients apply for treatment; he declared that complication, or to some temporary upset, such as indigestion.

I am fortunate in having beds of my own to look after, but as it happens these are nearly all semi- or greatly-advanced cases, some of which are received into the tuberculosis wards of our infectious diseases hospital within the borough, but others are housed in the municipal hospital already referred to. Emergency cases, such as that of a domestic servant with hæmoptysis, whose mistress desires her speedy removal to an institution, are taken into whichever hospital has a vacancy. Early cases we send away to sanatoria in various parts of the country, and cases of surgical tuberculosis in children and adults we send away to those hospitals specially dealing with such cases.

THE DISPENSARY

My dispensary is centrally placed and is readily accessible from all parts of the town. There are five clinics weekly, on three afternoons and two evenings, and every effort is made to enable the place to act as it is rightly intended to do under the tuberculosis scheme—namely, as a place for consultation and sorting out of cases—a clearing-house, in fact—not as an out-patient department for the perfunctory distribution of cod-liver oil and malt. I do not say that we do not give medicines to uninsured persons, but this is discouraged, patients being referred to their own medical attendant whenever possible.

After lunch I start at 2 P.M., the premises having been opened and gas-fires lit (in winter) by the dispensary nurse. Nearly all the cases come with a doctor's card or letter, which means a letter back to the sender with an expression of opinion and suggestions as to treatment, &c. The patient is first interviewed singly by the nurse who acts as a clerk, the necessary details being entered by her upon the blank dossier. She next weighs the patient, directs him or her into a dressing-room, and, if a female, comes into my consulting-room with her. The first patient to-day is a thin, under-nourished little girl of 7, recommended by one of the school medical officers. She is stated by her mother to have had a cough on and off for about two years, usually worse in the winter. The tonsils and adenoids had been removed a year ago. She had no temperature and there was no family history of tuberculosis. On examination there was nothing definite to be heard, and I could not even say that d'Espine's sign was positive. There were no visible or palpable glands. She may, of course, have an enlarged mediastinal gland which is pressing on the trachea, giving rise to the cough, but this can only be determined by an X-ray examination, which I propose to do. The next is a boy of 9, with a tag of exuberant granulations at the end of a scar on the side of his neck. The history was that a swollen gland had appeared in that region during the summer holidays, had burst, apparently without medical attention, and had left the usual ugly, broken-down, partially healed scar. He was referred to his own doctor.

The next is a problem, a tuberculous mother, with three small children, and a drunken husband who has also been mental—truly a case for the eugenists to shout over! At various times the family has been assisted by every humanitarian agency, both official and non-official, in the town with only temporary benefit. She has been sputum-positive and the whole family has been examined as contacts with negative result. One child, the eldest, was sent away by one agency to a boarding-school near London, but the father demanded her return; another was got into a children's home in the town, but the third refuses to leave his mother, and the parents continue to lead a cat-and-dog sort of existence—a pitiable state of affairs in which law and medicine seem able to do little. The next is a young woman in whom thoracoplasty has been performed for empyema, six years ago, with a very good result. She has been able to do a certain amount of domestic work in her mother's house, though there are still a few crepitations at the upper part of the affected lung. She looks very well, and is certainly a marvel considering what she has been through.

Here is a thin man, a war-pensioner, who had a four-figure position before the war. He has a slight cough, very scanty sputum which has been positive, but suffers from great fatigue on the slightest exertion. He is in a fairly comfortable position in life, living with relatives, and can take as much rest as is demanded, so he is really well off and does not need institutional treatment. Rather different is the case of this young man of 20, also thin and weedy, with a cough, night-sweats, and slight sputum of about two months' duration. He does not consider himself ill at all, nor does his father, but I had to tell the latter that there were early signs of disease at one apex, and that if this were allowed to go on without treatment matters would only get worse. His doctor and I agreed that sanatorium treatment was strongly indicated, and arrangements were made to get him away as soon as possible.

The next case, a woman of 19, the daughter of a tuberculous mother, whom she helped to nurse, revealed the sad fact that she herself had become a victim of the disease, but she was a home-loving girl and she did not wish to leave her mother. Besides, she had a good bedroom to herself and there was no evidence of privation. On examination I found a few crepitations at the right apex and the sputum was positive. There was slight evening pyrexia and also loss of weight. Her doctor, to whom I wrote about her condition, agreed with me that the only practical thing to do was to induce an artificial pneumothorax upon the affected side, provided that the other lung was good. I screened her a few days later and took a film, and as the left lung appeared to be healthy I took her into the hospital and induced an artificial pneumothorax with success. Several old cases followed, and after the clinic was over I went to the laboratory at our infectious diseases hospital, where I examine all the sputa of my own patients as well as specimens sent up by practitioners in the town, and stained several films.

CONTACT EXAMINATIONS

It may be urged that I have said nothing yet about the preventive aspect of my work, for surely that is equally, if not more, important than the treatment of those already affected. Well, suffice it to say that our staff of health visitors, my dispensary nurse, and myself do all in our power, by visitation and persuasion, to get contacts medically examined, either in their own homes or at the dispensary. In many cases the request is acceded to quite readily, but in others it seems that no amount of talking, even of the right kind, will induce some to be examined who undoubtedly should be. They plead all manner of excuses and some are most elusive, so that the ideal "march past" of possible and actual contacts, originally a regular slogan of the early days of the tuberculosis campaign, becomes a downright hunt, and even then the prey will not be tracked down. In all open cases it is imperative to get hold of young children whose susceptibility to "mass infection" is great. It is in cases of this kind that an after-care committee can be of great service, and I am fortunate in having one in this town, to which I am the honorary medical adviser. We are often successful in getting children from tuberculous households sent away to convalescent homes, or to be boarded out with some kind motherly person in the country. With some persons of an obstinate nature it is little use to adopt a bullying or a frightening attitude. It may take longer, but one is often more likely to win a case over for examination by a plainly reasoned statement about the manner in which infection is conveyed and avoided. To assist further in this direction we make free use of leaflets giving simple talks about consumption, what to do when one has got it, and how to prevent giving it to others as well as how to prevent people from becoming infected. It is found that personal talks in the home and at the dispensary, by the health decision of the insurance committee on this report has been taken. The matter was discussed at some length by the general purposes subcommittee of the London insurance committee after obtaining the opinion of both its service subcommittees. The medical service subcommittee thought the view of the Ministry was right; the pharmaceutical service subcommittee thought it was wrong. The former would like its reports issued as a separate document to members of the insurance committee, but not to the press. The latter said it was an established custom amongst local authorities to send the agenda paper of any of their meetings to the press at the same time as it was circulated to members, and was unaware of any reason for withholding from the press such information as was contained in its reports.

It seems that in Lancashire the press are requested to refrain from publishing or commenting upon any matters contained in the reports of the service subcommittees until confirmed or altered by the insurance committee. This was the first course advised at the meeting of the London general purposes subcommittee. After discussion, however, a majority of the subcommittee thought there should, in London, be no alterations of the present procedure, as it would be contrary to the public interest for the press not to be furnished with agenda papers at the same time as to the committee. A resolution to follow Lancashire's example was withdrawn, and at its next meeting the subcommittee decided to take no action on the suggestion that reports of the service subcommittee should not be issued to the press till after such reports had been considered by main committee and decision taken thereon. This resolution when it reached the insurance committee was carried without discussion.

The Ministry of Health may make the suggested alteration obligatory on insurance committees. Their letter hints at this, although it does not say so. It is obviously impossible to have one set of rules for the trial of an insurance doctor acting in one area and another set of rules in another area.

THE DOCTOR'S DAY

"Come, tell me how you live," I cried,
"And what it is you do!"

XI.—TUBERCULOSIS OFFICER

I DO nothing else but tuberculosis, day in day out, being a purely "specialist" officer attached to the health department of a large county borough, and I am clinically absolutely "on my own." When one has been in the tuberculosis service for nearly 20 years and is known to do nothing else, it is natural that one's colleagues in general practice in the town should refer their suspect and actual cases of tuberculosis to him who, by virtue of training, experience, and qualifications, may justly lay claim to the title of specialist in this disease. I am happy in the thought that my relations with all the doctors here are most cordial. It might be thought that such work must be unsatisfying and monotonous, but, indeed, it is actually far from being so. True, I sometimes feel that I am fighting against odds, but a pessimist should never become a tuberculosis officer, for even with modern weapons of warfare consumption still remains, if not the "captain," at least the "lieutenant" of the "men of death." I am far more sorry for my nurses in my tuberculosis wards, who are daily and hourly in close contact with more or less advanced cases of the disease—and who are bigger grumblers than consumptives?—than for myself.

ROUTINE

Here is an example of a day's routine work. On this particular morning I have my artificial pneumothorax clinic at the municipal hospital, which is some miles outside the borough boundary. I drive out by car, and the patients get there by bus or by train. At 10 A.M. screening begins, and the first case comes in. He is a man of 26, whose artificial pneumothorax was induced at one of the London hospitals, but he has recently come to live in this town, so I have to carry on with his refills. He has a fairly good right-sided collapse, the left showing merely the usual slight congestive hyperæmia; heart in good position. He subsequently took 300 c.cm. of air, and was left with a final pressure of 2 ±0. The next was a girl of 19, whose artificial pneumothorax was of a years' duration. She had recently had a chill, some pain in the side, and had had a temperature of 100° F. On the screen the right chest was seen to contain fluid giving the characteristic wave-like movement on shaking the body, but not a very large quantity. She was told to go home and rest and return in a week for rescreening. Subsequently the fluid increased so that I had to replace it with air, and her progress was good. It is strange how well many of these artificial pneumothorax cases do after having had an effusion, provided of course that it is not purulent. The next was the case of a man of 50, tall, asthmatic, with a tendency to stoop, and a worried look. I should not have been surprised if I had found radiographic evidences of tuberculosis, but the screening showed nothing definite. A film revealed some slight mottling at the left mid-zone, but his sputum has been negative on several occasions. Here is a youth of 19 with a bad family history, his father and one brother having had the disease. He had felt "run down"—an ominous expression which I never like to hear—for some few months past, and owned to have smoked about 20 cigarettes a day. Physical examination showed nothing definite, but I thought it imperative to X ray him, as it not infrequently happens that a film will reveal something suggestive of an early lesion when one can hear practically nothing with the stethoscope. However, the film showed nothing upon which I should have been justified in labelling him as tuberculous. Nevertheless, his doctor and myself will both watch him, and if necessary I shall rescreen him and take another film. This young lady looks the picture of health, is symptom-free, though 12 months ago she was sputum-positive. She went away to a sanatorium where an artificial pneumothorax was induced, and now she has a good uniform collapse, free from adhesions, which are the twin bugbear with fluid of all artificial pneumothorax work, and I gave her a (three-weekly interval) refill of 350 c.cm. Take it on the whole it is perfectly true, as one of my colleagues once wrote in *Tubercle*, that an artificial pneumothorax out-patient clinic is mostly a happy crowd, because each patient feels that the special treatment is really getting to grips with the disease, and also because, in the favourable cases, the sufferers are feeling well and are at work. One of my boys is a butcher in full work, another a labourer also (luckily) in permanent work. It is always sad when, as occasionally happens, one has to abandon the treatment owing to adhesions, or to the spread of disease in the opposite lung. Still it is agreed that artificial pneumothorax is the brightest spot in our modern therapy, and, personally, I enjoy this part of my work more than any other.

The screening over, the refills are given, men first and women afterwards, and in the work I am most ably assisted by one of the assistant medical officers of the hospital who is capable of acting for me in my absence. In practically all cases the patients are able to return home immediately after a refill. Only exceptionally is a little rest needed, and then it is generally owing to some threatened or actual

CORRESPONDENCE

MASKED HYPERTHYROIDISM

To the Editor of THE LANCET

SIR,—Dr. John Towers, in his paper (p. 67), and you, in a leading article (p. 91), have called attention to an important aspect of hyperthyroidism as a cause of heart disease. I believe that I was one of the earlier writers in this country to describe this particular aspect of thyroid disorder, and in a paper[1] recording two cases I referred to the article (quoted by Dr. Towers) by S. A. Levine and C. C. Sturgess, a reprint of which reached me soon after these cases had been under my care. In one of my cases the patient complained of the heat of the ward (in winter), and I have subsequently found the preference of such people for cold weather a useful indication of raised metabolism. I venture to quote the concluding paragraph of my article as evidence of my agreement with Dr. Towers's observations :

> "This type of hyperthyroidism is a subtle one, a most important one, and one the true nature of which is often overlooked. Suspect hyperthyroidism in all cases of fibrillation, tachycardia, and other cardiovascular disorders for which no other cause can be found and which do not respond to the usual remedies, and be fairly convinced of the accuracy of your diagnosis if only one or two of the many symptoms of hyperthyroidism are present."

I am, Sir, yours faithfully,
Norwich, Jan. 14th, 1933. H. J. STARLING.

DERMATITIS FROM DYED FABRICS

To the Editor of THE LANCET

SIR,—The valuable paper by Dr. E. M. Killick and Dr. J. T. Ingram in your issue of Jan. 14th (p. 77) calls for some comment, because it may tend to confuse the issue as between chemical and personal tests. The authors, as it seems to me, go beyond their brief, and would have one or the other as a causa causans of dermatitis resulting from the wearing of dyed garments. Personally, I have always employed both chemical tests on the garment and specific tests on the individual for idiosyncrasy. I am therefore well aware that idiosyncrasy plays an important part. The point, however, is this : There are certain methods of dyeing in which soluble oxidation products—e.g., of para- or meta-phenylenediamine are produced which are capable of giving rise to dermatitis in healthy controls. These can be withdrawn from fur—and I assume from other garments also—by prolonged washing. This is an expensive process and has frequently been omitted in the case of furs which have given rise to dermatitis. I have produced dermatitis by patch and scarification tests with these substances not only with the incriminated fur, but with the chemicals prepared in vitro. I have never, however, attempted to deny, nor so far as I can ascertain has anyone else, that idiosyncrasy to fabrics dyed with phenylenediamine or any other chemical does not occur. In many of my own cases I found such idiosyncrasy, and therefore absolved the fur.

The point is of something more than academic value. The fur trade is to be congratulated on having solved the problem of providing for persons of limited means garments which keep them warm and give them a pride in their personal appearance : and for this purpose para-phenylenediamine and its allies are customarily employed. The soluble intermediate oxidation products, however, are harmful and capable of causing dermatitis in subjects from whom idiosyncrasy is absent and failure to eliminate these has been judged in many legal causes to be evidence of negligence, and damages, often large, have been awarded because fur dermatitis may last for months or even years and reduce the sufferer to a wreck from constant irritation and sleeplessness.

To sum up. There are two causes for "fabric" dermatitis—namely chemicals which give rise to irritation of the skin in healthy controls, and which should have been removed from the fabric, and sensitisation which is attributable to the person and not the garment. The distinction is not difficult, for appropriate and reliable tests are available for the purpose. Whether the garment is made of fur or other fabric does not seem to matter very much.

I am, Sir, yours faithfully,
A. KNYVETT GORDON, M.B.
Bedford-square, W.C., Jan. 16th, 1933.

PROGRESSIVE POST-OPERATIVE GANGRENE OF THE SKIN

To the Editor of THE LANCET

SIR,—It was most interesting to read Mr. F. Hector Scotson's report of a case in your last issue, as the condition is more common than references to the literature would lead one to suppose. The reasons are doubtless due to the obscurity of the cause and the lack of success from treatment.

In my experience gangrene of the skin may follow an operation, usually for appendicitis, or it may occur spontaneously, and then most frequently in the genito-crural region. The appendix is most often a gangrenous one in the process of which the *Bacillus morgan*, a derivative of the *B. proteus vulgaris*, plays a rôle. A case of the spontaneous form, unique, because of the multiplicity of the lesions, was described in *The Nature of Disease Journal* (p. 120). The cause appears to be the *Bacillus gangrenæ cutis*, a name, which I believe was first given by Milian in Paris to the bacillus held to be responsible for the spontaneously occurring genito-crural form. Balog published one of these genital cases in 1931. The *B. gangrenæ cutis* belongs to the proteus group of micro-organisms, and has most probably had origin with Ducrey's bacillus from the *B. morgan*. There is a close similarity between the gangrenous lesion and ulcus molle serpiginosum, of which I published the first description in this country in 1914. The most successful treatment for gangrene of the skin is novarsenobenzene, injected intravenously. The drug is almost a specific and does away with all need for the cautery. The drug best suited for ulcus molle serpiginosum is tartar emetic injected intravenously.

I am, Sir, yours faithfully,
J. E. R. McDONAGH.
Wimpole-street, W., Jan. 13th, 1933.

DOSAGE OF INSULIN

To the Editor of THE LANCET

SIR,—May I, as another "diabetic doctor" on insulin for ten years, present a more fortunate experience of the successful standardisation of British insulin than is expressed by my colleague in his letter published to-day. In 1923 and 1924, the early days of insulin, I gave clear evidence from visitors and by myself, are better than set lectures or the display of cinema films, for at the latter one finds only the converted attend, and it is well known that cinema proprietors do not find such propaganda films at all profitable.

---

[1] Clin. Jour., Feb. 8th and 15th, 1928.

THE INTEREST OF THE WORK

By way of compensation for any distasteful portion of the work of a tuberculosis officer there is its variety, for any clinic will provide plenty of material of interest, and so far as treatment or research are concerned I have entire liberty to do what I like, and since I have charge of beds I can admit my own cases and watch the effect of a given remedy. I see, too, a large number of non-tuberculous conditions —e.g., morbus cordis, neurasthenia, anæmia, bronchiectasis, bronchial asthma—so that it cannot be said that the work is wanting in clinical interest. Then, too, there is always the pleasure of seeing a really early case respond to prompt treatment.

From the public health aspect one cannot but lament the present economic stress and unemployment resulting in overcrowding and a chronic state of malnutrition, especially among children. The improvement that takes place with better housing and feeding is a sufficient indication of the main lines upon which legislation, hand in hand with philanthropy, will be found to be of practical service in the way of prevention in the future. To be able to render help to the practitioner, as well as to the patient, in a personal consultation at the bedside is another of my pleasures, and here again one feels, whether in confirming an already expressed opinion or in pronouncing judgment in a diagnosis, that it is worth while to be a specialist in the work instead of having it tacked on, so to speak, to a post in which one has to do schools, maternity work, infant welfare, and all the other sundries that go to make the work of a combined medical officer a glorious mixture of activities.

I have omitted to mention one thing which all my colleagues in the tuberculosis service deplore —namely, the large amount of clerical work, form writing, and the making of numerous returns to one's own as well as outside authorities, which has to be done. From various considerations it is not always possible to employ adequate clerical assistance, but it does seem to detract from the work when one has, as I have, to enter a name and address, in the case of a new patient, at least three times and sometimes more. To many medical men and women, not specially gifted with the mathematical mind, the filling up of the annual returns is nothing more nor less than a nightmare, but no doubt it is regarded as a pleasure by some.

Enough has been said to give some idea, I trust, of the daily work and routine of a tuberculosis officer, but let no one take up such an appointment unless he or she be a confirmed optimist.

PUBLIC HEALTH SERVICES

Influenza

The spread of influenza over the country is taking the course rendered familiar by previous winter epidemics, leaving room for doubt and uncertainty as to whether this or that locality will suffer sooner or more than others. Taking the 118 great towns as a whole, a sharp rise in reported deaths from influenza was apparent in the return for the week ended Dec. 10th, 1932, the figures [for successive weeks from Dec. 3rd on being 33, 68, 85, 120, 303, 681, and 1041. In London no indication of unusual incidence was seen until the week ended Dec. 31st, the figures for deaths from influenza for the last four weeks being 8, 25, 93, and 242. The epidemic began in the north; Glasgow reported 86 deaths already in the week ended Dec. 24th; Newcastle-on-Tyne, Liverpool, and Manchester suffered early, and are now through the worst. In Birmingham the epidemic started quite suddenly about 12 days before Christmas, when 10 per cent. of the employees of utility services were disabled; the maximum was reached shortly after Christmas, and the decline was rapid. There, as elsewhere, the epidemic was described as relatively mild, the incidence of pneumonia being quite small. Up to the week ended Dec. 31st the actual deaths from acute pneumonia in London were below those to be expected from the ten-year median value; in the following week London was 11 per cent. above expectations, England and Wales 60 per cent. above. In London the influenza has taken two familiar types, alimentary and respiratory, and, as mentioned in a clinical note on p. 141, the features of these two types have remained sharply distinct. Many hospitals in London and large centres have passed through anxious times owing to the numbers of the nursing staff down with influenza at the same time, but no serious results have been reported. Judging by reports, the west country has so far escaped, with the exception of Exeter.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED JAN. 7TH, 1933

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 16 (last week 19); scarlet fever, 1802; diphtheria, 870; enteric fever, 21; acute pneumonia (primary or influenzal), 2816; puerperal fever, 37; puerperal pyrexia, 132; cerebro-spinal fever, 38; acute poliomyelitis, 9; acute polio-encephalitis, 2; encephalitis lethargica, 7; dysentery, 5; ophthalmia neonatorum, 72. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on Jan. 10th–11th was as follows:—Small-pox, 52 under treatment, 7 under observation (last week 75 and 2 respectively); scarlet fever, 1790; diphtheria, 1678; enteric fever, 12; measles, 267; whooping-cough, 491; puerperal fever, 31 (plus 13 babies); encephalitis lethargica, 230; poliomyelitis, 3; "other diseases," 286. At St. Margaret's Hospital there were 15 babies (plus 7 mothers) with ophthalmia neonatorum.

Deaths.—In 117 great towns, including London, there was no death from small-pox, 3 (1) from enteric fever, 25 (0) from measles, 12 (1) from scarlet fever, 34 (8) from whooping-cough, 40 (9) from diphtheria, 37 (8) from diarrhœa and enteritis under two years, and 681 (93) from influenza. The figures in parentheses are those for London itself.

Fatal cases of influenza were reported from 88 great towns outside London, the largest number of deaths being 163 at Birmingham, 45 at Newcastle-upon-Tyne, 24 at Sunderland, 23 at Liverpool, 22 at Manchester, 19 at Portsmouth, 14 at Leeds, 13 at Southampton, 12 each at Gateshead and Worcester. The fatal cases of enteric fever occurred at Wigan and Worcester. Measles caused 8 deaths at Birmingham, 4 at Leicester, 3 each at Gateshead and Liverpool. Diphtheria was credited with 4 deaths at Bootle, 3 at Leeds. In the same week Glasgow reported only 36 deaths from influenza, and 13 from whooping-cough.

The number of stillbirths notified during the week was 267 (corresponding to a rate of 39 per 1000 total births), including 50 in London.

COLDSTREAM COTTAGE HOSPITAL.—Last year there were 155 in-patients, an increase of 35, and their average stay rose from 19½ to nearly 24 days. There were 60 major operations.

GASTROSTOMY VERSUS INTUBATION

To the Editor of THE LANCET

SIR,—In his interesting letter Mr. E. Watson-Williams states as one of the disadvantages of gastrostomy :—

> Food is not taken by the natural channel, and is *not tasted*. The psychic effect, when the patient realises that he will never taste or swallow anything again, is often very bad. (Italics mine.)

During my hospital practice I tried to overcome this difficulty by the following method: When feeding by gastrostomy I always put in the patient's mouth one or two table-spoons of the food from the syringe, asked him to chew it properly and slowly, and then to spit it out with the saliva. I was brought to this simple method by the remark of one of our patients who was being given minced veal, "What a pity I cannot taste the meat; I like it so much." The patients were always very pleased and sometimes asked for some more spoonfuls.

I am, Sir, yours faithfully,

V. SUK.

Masaryk University Anthropological Institute,
Czechoslovakia, Jan. 9th, 1933.

PAIN AND THE DOCTOR

To the Editor of THE LANCET

SIR,—Prof. Robertson often asserted that "all pain is mental," and those who practise his branch of medicine mostly agree with that dictum. If that is accepted, how does it work in with the various statements as they appear in an article in your issue for the 14th inst. under the above heading? Are not such statements very much on a line with the statement often heard from a nurse in reply to a doctor's inquiry—viz., "he has no temperature."

Is it not as futile to expect to avoid pain as it is to expect to avoid a temperature?

I am, Sir, yours faithfully,

Hove, Jan. 16th, 1933. E. ROWLAND FOTHERGILL.

NEW PREPARATIONS

To the Editor of THE LANCET

SIR,—Under this heading in your issue of Dec. 24th last (p. 1416) the statement is made that Essogen is ten times U.S. cod-liver oil strength. The official U.S.P. standard for cod-liver oil is that it should contain 50 curative doses for rats per gramme—i.e., the effective rat unit is 20 mg. Admittedly this standard is a very low one—much lower than the minimum blue value of ·6 specified in the new issue of the British Pharmacopœia. Exact comparison is impossible because of the weaknesses of the test specified by the U.S.P., but Essogen on the basis of blue value is more than 300 times the B.P. standard, and therefore must be of even higher relative potency as compared with the U.S.P. standard.

We are, Sir, yours faithfully,

LEVER BROTHERS, LIMITED.

Biological Laboratories, Port Sunlight,
Cheshire, Jan. 12th, 1933.

VENOUS STAGNATION FROM GRAVITY

To the Editor of THE LANCET

SIR,—In his article on Phlebitis in THE LANCET of Jan. 14th, Mr. A. Dickson Wright mentions stagnation in the veins, due to rest in bed and cessation of muscular contractions, as a contributory factor. The following movement which can be made periodically by the patient is important for prophylaxis. The patient should lie or recline with his foot against a firm surface, such as a bolster or a bed-table up-ended with a pair of legs under the mattress. The big toe and heel are then applied to this surface, arching up the dorsum of the foot by means of the intrinsic muscles, and the back of the knee is pressed down against the mattress. There should be a slight extension of the hip-joint, and the patient should not press back his head and shoulders but should momentarily increase the pressure between the lumbar region and the mattress.

During this very mild activity a large proportion of the muscles in the limb are in use. Apart from the prime-movers the following muscles coöperate · those whose tendons cross the ankle-joint, muscles in the thigh and buttocks, also those in the lower abdominal wall. An adequate pumping effect on the venous system occurs throughout the limb with a minimum expenditure of energy. The psychological effect of getting the feet against a firm surface, and of doing something to shorten convalescence, encourages the patient to make periodically this small effort.

I am, Sir, yours faithfully,

London, Jan. 13th, 1933. JAMES K. MCCONNEL.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

The following Surg. Lts. (D.) to be Surg. Lt.-Comdrs. (D.): S. Mawer, L. F. Fairey, L. A. Moules, and G. Baker.

F. W. Chippindale to be Surg. Lt.

The following appts. are notified: Surg. Lt.-Comdrs. W. Flynn to *President* for course and to *President* for Experimental Stn., Porton; R. L. G. Proctor to *Vernon* and A. G. L. Brown to *Despatch*.

Surg. Capts. H. E. E. Stephens to *Victory*, for Haslar Hospital; and F. J. Gowans and A. G. V. French to *Egmont*, for *Maine* and R.N. Hospital, Malta, respectively.

Surg. Comdrs. F. H. Vey to *Pembroke*, for Chatham Dockyard; and F. E. Fitzmaurice to *Leander*, on commg.

Surg. Lts. M. G. Ross to *Glorious*; M. J. Brosnan to *Vivid*, for Devonport Barracks; A. S. Cox to *Valiant*; and T. L. Cleve to *Maine*.

ROYAL NAVAL VOLUNTEER RESERVE

Surg. Capt. R. J. Willan is placed on the retd. list.

Surg. Lt. F. W. Chippindale, Commission terminated on transfer to R.N.

Surg. Lt. R. H. Berry is apptd. to *Victory*, for Haslar Hospital.

TERRITORIAL ARMY

Lt. J. V. Morris to be Capt.

INDIAN MEDICAL SERVICE

Lts. (on prob.) Sangham Lal and B. L. Taneja to be Capts (prov.) (on prob.).

ACCIDENT CASES AT RATE-AIDED HOSPITALS.—At a recent health committee meeting of the Essex county council it was reported that certain insurance companies had refused to meet claims made upon them under Section 36 (2) of the Road Traffic Act, 1930, in connexion with accident cases admitted to the committee's institutions, on the grounds that the Section did not apply to rate-aided hospitals. From counsel's opinion, since obtained, it would appear that the committee has a right of recourse to the insurance companies for a payment up to £25 in each case where it can be proved that liability attaches to a company under a policy, and when the person concerned or his relatives are unable to meet the cost of maintenance. The committee has therefore instructed its collectors in all cases where the cost of maintenance cannot be obtained from the patient themselves to apply again to the insurance companies involved. If satisfaction cannot be obtained, the committee intends to settle the matter by bringing a test case in the High Court.

clinical tests on myself and a few patients, that variations of 60 per cent. from batch to batch of both English and American insulin were not uncommon. This was immediately taken up by the Medical Research Council and the manufacturers, and a biological test on animals was worked out which narrowed the variations to under 10 per cent., which is the smallest variation that I can detect by the most careful work on diabetics. Since then I have always been on the lookout for changes in new batches. I use only two makes of insulin; between 1926 and 1929 there were three bad batches. Since then I have noticed no variation in them. Whenever a reliable patient suspects the uniformity of any new batch, as not infrequently happens, I always test it out, and the evidence usually shows the patient, and not the insulin, to be wrong. In patients on the most careful diet, insulin requirements often vary by more than 10 per cent. from day to day, depending on natural changes in foods (as you point out), and in activity and general health.

I know that the reliability of British insulin has always been recognised in Europe, and it is pleasing to note in foreign protocols how often it is used in accurate experimental work instead of the insulin produced in that country. I am a little surprised to gather that my colleague has so many unfortunate experiences with different batches of insulin, because, if he reserves, as he says, a whole batch for his personal use, that might be expected to be an adequate supply for some 50 years.

I am Sir, yours faithfully,

Harley-street, W., Jan. 14th, 1933. R. D. LAWRENCE.

"DISEASES OF THE BLOOD"

To the Editor of THE LANCET

SIR,—I have read with much interest the review of the second edition of my book "Diseases of the Blood," in your issue of Jan. 7th (p. 26). I was particularly charmed to see your reviewer's statement that "Misstatements of facts . . . are unfortunate"; I presume that no one could deny this, but it is especially unfortunate when such misstatements appear in a review. I am accused of having omitted reference to the value of iron in post-hæmorrhagic anæmia, but reference to the index of my book shows an entry "Iron, after hæmorrhage, 41." On this page I indicate the need for iron in cases of acute post-hæmorrhagic anæmia, and on the next page, in connexion with chronic post-hæmorrhagic anæmia, I assert that the medicinal treatment is the same as in the acute form. I also refer to the value of whole liver and of certain special forms of liver extract; a cross reference to p. 179 indicates the paragraph in which the essential characters of such an extract are described.

With reference to the anæmia of infancy. Your reviewer appears to contend that, because the red corpuscles rise after administration of iron, the anæmia is necessarily due purely to a deficiency of that metal; it may be so, but I doubt it, and do not feel that the controversy has been much advanced by his pontifical statement. I think that if he had read the book with more care he would have found that cases of acholuric jaundice with practically no splenomegaly are mentioned; equally, there is reference to the almost completely normal character of the blood during remissions.

I am unrepentant about my statement that "We are completely ignorant as to the mechanism by which the number of leucocytes in the circulation is regulated," but, of course, am well aware of the fact that nucleotide is capable of altering the number of the white cells in the blood. I plead guilty to the slip concerning phospholipin in the typical cells of Gaucher's disease, but do not feel that this is of much importance "in a book which will appeal to the general practitioner."

I should be very glad to hear the comments of your reviewer on my alleged "misstatements of facts."

I am, Sir, yours faithfully,

A. PINEY.

Pathological Department, The Cancer Hospital,
Fulham-road, London, S.W., Jan. 11th, 1933.

*** We should be loth to agree with Dr. Piney that scientific accuracy is not of much importance in a book intended for the general practitioner; we feel he should be given clear indications of treatment in common conditions. In post-hæmorrhagic anæmias iron and whole liver in large doses are of proved therapeutic value. Dr. Piney does briefly mention that iron should be given—we frankly admit the oversight—but he gives no indication of the extreme importance of adequate and persistent dosage, nor of the uselessness of certain of the preparations on the market. In acholuric jaundice he states that the blood always shows some deficiency of hæmoglobin and corpuscles, although Gansslen has reported a large group of cases with no anæmia. The fragility of the red cells does not invariably decrease after operation, it may indeed increase. Hyaline degeneration of the pulp arterioles, described as a common histological feature of the spleen in this disease, occurs in so many conditions as to be hardly characteristic of any one disease. The work of Doan and his collaborators on the control of circulating white cells merits discussion, even if Dr. Piney is unconvinced as to its interpretation; readers may be glad to turn to the admirable summary of the position in *Jour. Amer. Med. Assoc.*, 1932, xcix., 194.—ED. L.

CONTRACEPTIVES

To the Editor of THE LANCET

SIR,—It is not generally realised that at least 175 chemical contraceptives may be found upon the market. Many of these appear to depart markedly from the desired standards laid down by the leading workers in this field, and a similar state is to be found when mechanical methods are considered. It is for this reason that several firms have formed themselves into a group with the following objects in view: (1) to maintain a certain standard of purity and excellence in manufacture; (2) to focus attention upon such methods as are likely to meet with general success and to see that they are harmless to the user, easy to apply, and reasonable in cost; (3) to study the question of packing and deterioration and the issuing of seemly literature and advertising.

This group is the direct result of the museum which I have recently formed in the department of public health of the London School of Hygiene and Tropical Medicine where the many aspects of this difficult and multi-sided subject are dealt with. The formation of a similar group in the United States and on the continent is under consideration, and I submit that this is a most important step which not only will help to remove the stigmas which have so long existed, but may well aid contraception to become a worthy branch of preventive medicine.

I am, Sir, yours faithfully,

CECIL I. B. VOGE.

London School of Hygiene and Tropical Medicine,
Keppel-street, W.C., Jan. 13th, 1933.

GASTROSTOMY VERSUS INTUBATION

To the Editor of THE LANCET

SIR,—In his interesting letter Mr. E. Watson-Williams states as one of the disadvantages of astrostomy :—

> Food is not taken by the natural channel, and is *not tasted*. he psychic effect, when the patient realises that he will ever taste or swallow anything again, is often very bad. Italics mine.)

During my hospital practice I tried to overcome his difficulty by the following method: When eeding by gastrostomy I always put in the patient's mouth one or two table-spoons of the food from he syringe, asked him to chew it properly and lowly, and then to spit it out with the saliva. I was brought to this simple method by the remark of ne of our patients who was being given minced eal, "What a pity I cannot taste the meat; I like t so much." The patients were always very pleased and sometimes asked for some more spoonfuls.

I am, Sir, yours faithfuly,

V. SUK.

Masaryk University Anthropological Institute,
Czechoslovakia, Jan. 9th, 1933.

PAIN AND THE DOCTOR

To the Editor of THE LANCET

SIR,—Prof. Robertson often asserted that "all pain is mental," and those who practise his branch of medicine mostly agree with that dictum. If that is accepted, how does it work in with the various statements as they appear in an article in your issue for the 14th inst. under the above heading? Are not such statements very much on a line with the statement often heard from a nurse in reply to a doctor's inquiry—viz., "he has no temperature."

Is it not as futile to expect to avoid pain as it is to expect to avoid a temperature?

I am, Sir, yours faithfully,

Hove, Jan. 16th, 1933. E. ROWLAND FOTHERGILL.

NEW PREPARATIONS

To the Editor of THE LANCET

SIR,—Under this heading in your issue of Dec. 24th last (p. 1416) the statement is made that Essogen is ten times U.S. cod-liver oil strength. The official U.S.P. standard for cod-liver oil is that it should contain 50 curative doses for rats per gramme—i.e., the effective rat unit is 20 mg. Admittedly this standard is a very low one—much lower than the minimum blue value of ·6 specified in the new issue of the British Pharmacopœia. Exact comparison is impossible because of the weaknesses of the test specified by the U.S.P., but Essogen on the basis of blue value is more than 300 times the B.P. standard, and therefore must be of even higher relative potency as compared with the U.S.P. standard.

We are, Sir, yours faithfully,

LEVER BROTHERS, LIMITED.

Biological Laboratories, Port Sunlight,
Cheshire, Jan. 12th, 1933.

VENOUS STAGNATION FROM GRAVITY

To the Editor of THE LANCET

SIR,—In his article on Phlebitis in THE LANCET of Jan. 14th, Mr. A. Dickson Wright mentions stagnation in the veins, due to rest in bed and cessation of muscular contractions, as a contributory factor. The following movement which can be made periodically by the patient is important for prophylaxis. The patient should lie or recline with his foot against a firm surface, such as a bolster or a bed-table up-ended with a pair of legs under the mattress. The big toe and heel are then applied to this surface, arching up the dorsum of the foot by means of the intrinsic muscles, and the back of the knee is pressed down against the mattress. There should be a slight extension of the hip-joint, and the patient should not press back his head and shoulders but should momentarily increase the pressure between the lumbar region and the mattress.

During this very mild activity a large proportion of the muscles in the limb are in use. Apart from the prime-movers the following muscles coöperate: those whose tendons cross the ankle-joint, muscles in the thigh and buttocks, also those in the lower abdominal wall. An adequate pumping effect on the venous system occurs throughout the limb with a minimum expenditure of energy. The psychological effect of getting the feet against a firm surface, and of doing something to shorten convalescence, encourages the patient to make periodically this small effort.

I am, Sir, yours faithfully,

London, Jan. 13th, 1933. JAMES K. MCCONNEL.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

The following Surg. Lts. (D.) to be Surg. Lt.-Comdrs. (D.): S. Mawer, L. F. Fairey, L. A. Moules, and G. Baker.

F. W. Chippindale to be Surg. Lt.

The following appts. are notified: Surg. Lt.-Comdrs. W. Flynn to *President* for course and to *President* for Experimental Stn., Porton; R. L. G. Proctor to *Vernon* and A. G. L. Brown to *Despatch*.

Surg. Capts. H. E. E. Stephens to *Victory*, for Haslar Hospital; and F. J. Gowans and A. G. V. French to *Egmont*, for *Maine* and R.N. Hospital, Malta, respectively.

Surg. Comdrs. F. H. Vey to *Pembroke*, for Chatham Dockyard; and F. E. Fitzmaurice to *Leander*, on commg.

Surg. Lts. M. G. Ross to *Glorious*; M. J. Brosnan to *Vivid*, for Devonport Barracks; A. S. Cox to *Valiant*; and T. L. Cleve to *Maine*.

ROYAL NAVAL VOLUNTEER RESERVE

Surg. Capt. R. J. Willan is placed on the retd. list.

Surg. Lt. F. W. Chippindale, Commission terminated on transfer to R.N.

Surg. Lt. R. H. Berry is apptd. to *Victory*, for Haslar Hospital.

TERRITORIAL ARMY

Lt. J. V. Morris to be Capt.

INDIAN MEDICAL SERVICE

Lts. (on prob.) Sangham Lal and B. L. Taneja to be Capts. (prov.) (on prob.).

ACCIDENT CASES AT RATE-AIDED HOSPITALS.—At a recent health committee meeting of the Essex county council it was reported that certain insurance companies had refused to meet claims made upon them under Section 36 (2) of the Road Traffic Act, 1930, in connexion with accident cases admitted to the committee's institutions, on the grounds that the Section did not apply to rate-aided hospitals. From counsel's opinion, since obtained, it would appear that the committee has a right of recourse to the insurance companies for a payment up to £25 in each case where it can be proved that liability attaches to a company under a policy, and when the person concerned or his relatives are unable to meet the cost of maintenance. The committee has therefore instructed its collectors in all cases where the cost of maintenance cannot be obtained from the patient themselves to apply again to the insurance companies involved. If satisfaction cannot be obtained, the committee intends to settle the matter by bringing a test case in the High Court.

OBITUARY

SIR ROBERT JONES, Bt., Ch.M. Liverp., F.R.C.S. Eng.

LATE ADVISER IN ORTHOPÆDIC SURGERY, THE MINISTRY OF PENSIONS, AND INSPECTOR OF MILITARY ORTHOPÆDICS, A.M.S.

WE regret to record the death of the great orthopædic surgeon, Sir Robert Jones, which occurred on Saturday last, Jan. 14th, at Bodynfod Hall, Llanfechan, the house of his son-in-law. The medical profession has lost in him the most prominent British figure in orthopædics, and for his services to the wounded in the war the country owes him an unpayable debt.

Robert Jones was born at Rhyl in 1858 the son of a father bearing the same name; his mother was Miss Mary Hughes, member of a neighbouring family. Privately educated, he received his medical training at the Universities of Edinburgh and Liverpool, and qualified in 1878 as M.R.C.S., proceeding later to the fellowship of the Edinburgh College of Surgeons. He received at the outset of his professional career the impetus which led later to his distinguished position. He worked as apprentice to his uncle, Hugh Owen Thomas, the inventor of the Thomas's splint, who was the son of a famous and skilful bone-setter; so all that the unqualified manipulator had to teach was known from the start of his career to Robert Jones, who, moreover, always acknowledged his debt to this traditional and empiric learning. He commenced practice in Liverpool, and after holding some junior appointments quickly obtained a place first on the staff of the Stanley Hospital, and later on that of the Royal Southern Hospital.

SIR ROBERT JONES

[Photograph by Brooke Hughes

It was some time before his unusual grasp of the principles and his ready inventiveness in the treatment of orthopædic cases were perceived outside his own centre. His fellow orthopædists, however, soon came to regard him as a pioneer, recognising the practical nature of much of his original technique, and his skill alike in diagnosing the conditions and suggesting the course of treatment to be adopted. In those early days America and the continent knew Robert Jones better than did his own country. It was not so much by innovations that he attracted attention as by his skilful application of the old knowledge to meet the advance of general therapeutics. An increasing familiarity among medical men with the problems presented by the deformities and distortions following hereditary conditions or disabilities acquired in childhood called for developments in orthopædic work that had hitherto been unthought of; Robert Jones did the thinking, and by speech, pen, and clinical example inspired many followers. Some years before the European War he was a member of French, German, Swedish Italian, and American orthopædic societies, and when, in 1912, was invited to deliver the annual oration at the Medical Society of London he chose for his subject the surgical treatment of infantile paralysis, and threw powerful light upon the possibilities of effective treatment in many situations where surgical interference had appeared disappointing. His particular experience was gained in his wards at the Royal Liverpool County Hospital at Heswall, which owed its real inception, in 1909, to Robert Jones, and which is now amalgamated with the Liverpool Children's Infirmary. In 1913 he was president of the orthopædic section of the International Congress of Surgeons, held in London, and when the war broke out he had attained to such a position as to make him the ideal leader in the movement for the furnishing of organised orthopædic assistance to the wounded and injured in the war.

At the beginning of the war, when the wounded poured into this country as the result of great casualties and enforced retreats, all the British hospitals were soon full to overflowing, and auxiliary hospitals and command depôts became equally crowded. At the same time so large a proportion of surgeons were on service abroad that organisation for the treatment of this inrush of sufferers was wellnigh impossible to institute. This was Robert Jones's opportunity and magnificent use he made of it. The first task was to collect the cases most requiring attention. Investigation showed that in all the hospitals and depôts there were victims of ununited or badly united fractures, or of ankylosis, rendering function almost nugatory; cases, also, where badly devised operations had resulted in useless or flail joints, and cases of undiagnosed nerve lesions. In other cases operations had been well performed, but the appropriate after-treatment was wanting. In short, orthopædic surgery for the benefit of our soldiers was not being properly practised, and could not be properly carried out upon individual cases scattered all over the country by practitioners who did not claim to have any particular familiarity with the conditions to be met or the best methods of meeting them. It was then that the War Office decided that an effort should be made to segregate groups of cases into especially staffed and equipped centres, where continuity of treatment could be secured for such cases as injuries to peripheral nerves, ununited and malunited fractures, injuries to joints, and cases likely to result in deformities of the extremities. The first centre established was the hospital at Shepherd's Bush. Here Robert Jones started his great endeavour, aided by a band of enthusiastic assistants, many of them Americans, whose country had not yet espoused the cause of the Allies. The amount of good done was incalculable, and went on there and at the numerous other centres for many years, to the benefit of these men now pensioners or seeking to regain civilian employment. Indeed the development of orthopædic surgery under the urgent and tragic circumstance of the war became a striking feature in surgical science, expanding by rapidly increasing strides and coming to embrace a scope and range unthought of. The need for increased knowledge brought with it new theories and new practices based on pathological and physiological observation. Appliances for restoration of function and for re-education were soon forthcoming, and it became clear—for the first time to many doctors as well as to the public—that orthopædic surgery was not a story of special splints or of remedying particular deformities, but covered the large range of surgery implied in the restoration of function to nerves and muscles in deformed or disabled limbs. Three years after the cessation of hostilities Robert Jones edited the "Orthopædic Surgery of Injuries," written by his own colleagues attached to the orthopædic centres, which later became the special military surgical hospitals, and in a modest preface outlined the activities of which he himself was a chief promoter. At these hospitals there were eventually no less than 30,000 beds, a figure which gives some idea of the magnitude of the activities inspired by and largely controlled by Robert Jones.

On his seventieth birthday a group of surgeons, friends, and colleagues of many nationalities entertained Robert Jones to dinner and presented him with the Robert Jones Birthday Volume, a collection of 25 original essays bearing in different directions on the specialty of orthopædics, and inspired by the work done in coöperation with or at the instigation of their guest. At this dinner Lord Moynihan, then President of the Royal College of Surgeons of England, delivered a short address on Robert Jones, describing him as prophet, high priest, and practitioner, and setting out his personal qualities in the words: "Robert Jones," said Lord Moynihan, "speaks ill of no man. He seeks and finds good in all things and in all men. He sets an ideal and a standard of action in friendship which all strive to reach when with him. In a long and very intimate friendship I have never heard an unjust criticism, a cruel jibe, or a word of bitter cynicism on his lips. He covers his displeasure or stern disapproval by silence, or a restrained reproof that is often weightier than a torrent of words from others. His personality radiates cheeriness, good temper, and goodwill. All men are attracted by him, and in war-time conflicting temperaments found in him something that appeased their differences, assuaged animosities, and encouraged a desire for friendliness. He was then called upon to rule in various places, over colleagues at first unfriendly, openly antagonistic, indifferent to his rule, or incredulous of his practice. We were all amazed at his success in overcoming very real difficulties by gentleness, sympathy, a true understanding of the minds of others, and a tactfulness which in times of crisis was almost magical." None of those who knew Robert Jones personally would wish to have a syllable altered in this estimate of his actions and of the spirit which inspired them.

The honours which fell upon him in recognition of the work done before, during, and after the war were numerous. He received a C.B. in 1917, and in the same year was knighted. Two years later he was appointed K.B.E., and in that year was elected to the Fellowship of the English and the Irish College of Surgeons, being given also the American Distinguished Service Order. The Universities of Wales, Aberdeen, Liverpool, Harvard, Smith, and Yale gave him honorary doctorates, and the American College of Surgeons elected him a Fellow. He was appointed Knight of Grace of St. John of Jerusalem and consulting orthopædic surgeon to St. Thomas's Hospital. In 1926 he received his well-earned baronetcy. Of all these honours bestowed by the State and by his profession, it can be truly said that he earned the distinctions and that his colleagues rejoiced in his reception of them.

Sir Robert Jones married Susie, daughter of Mr. William Evans, of Liverpool, who died in 1918, and by whom he had one son, and a daughter, the wife of Mr. Frederick Watson, of Bodynfod Hall, Montgomeryshire, a champion of the cause of crippled children, a partner in the publishing house of James Nisbet and Co., and a well-known author.

RICHARD GILL, F.R.C.S. Eng.

Mr. Gill, who was for 35 years administrator of anæsthetics at St. Bartholomew's Hospital, and had been living in retirement since 1916, died at Shaftesbury on Jan 13th, after a short illness.

Born in 1856, Richard Gill gained the preliminary scientific exhibition at St. Bartholomew's Hospital in October, 1874. He went on to win most of the other scholarships open to him, and at the University of London took many honours in succession at the final B.Sc. in 1878, M.B. in 1879, and B.S. in 1880. He was admitted a Fellow of the Royal College of Surgeons of England in 1881, having passed the necessary examinations before he had attained the legal age of 25, and without presenting himself for the diploma of M.R.C.S. After being house physician at the Great Northern Hospital he became house surgeon to Sir William Savory at St. Bartholomew's Hospital, being the last to serve without an assistant house surgeon and to have a "take in" lasting a whole week. In 1881 he was appointed assistant chloroformist to Joseph Mills, the first whole-time anæsthetist to the hospital, succeeding him in 1893, when he was appointed chief chloroformist; the title of his appointment was soon changed to administrator of anæsthetics and demonstrator of anæsthetics in the medical school. He resigned both positions in 1916, when he was elected a governor of the hospital.

MR. GILL

[*Photograph by H. W. Barnett*

As an anæsthetist Richard Gill devoted his whole working life to St. Bartholomew's Hospital. He was an extremely fine administrator; it was an education in itself to see him give chloroform in a long and difficult abdominal operation. Requiring only a drop bottle and a small square of lint he would produce perfect anæsthesia and relaxation with a minimum quantity of the drug. He was equally successful with gas and ether administered with Clover's apparatus or by means of a small bag. As an anæsthetist he insisted that the patient should be watched carefully during the whole period of administration, and emphasised the necessity of considering him as an individual rather than as a machine to be kept in [illegible] of insensibility. He practised the axiom which he taught that automatic breathing is the true sign of anæsthesia. As a teacher he was excellent; as a lecturer he was difficult to follow and was unable to hold his audience, for his brain worked faster than his tongue. It happened from time to time when he was lecturing that he would pause, and after a longer or shorter interval would continue some sentences ahead of where he had stopped, leaving his hearers to fill up the gap for themselves. At the beginning of the war he was attached as anæsthetist to the First London General Hospital with the rank of Captain R.A.M.C. (T.), but found himself unable to adapt himself to military discipline.

A colleague writes: "In early life Gill had a remarkable power of assimilating facts which he could rapidly reproduce on paper, and he thus made an admirable examinee. Of this faculty he made little use in after life. He was wholly without ambition, and was content to lead the placid life of a philosopher when he might have enjoyed the stirring existence of a surgeon in the active practice of his profession. Averse from society, and somewhat of a recluse, he was but little known even to the men of his own generation. The few who knew him became his staunch friends, for they recognised his strict integrity and his entire absence of self-assertion."

Mr. Gill married Elizabeth Ann, daughter of John S. Bostock, M.R.C.S., who practised for many years at Horsham in Sussex. There were no children of the marriage.

WILLIAM GALBRAITH, L.R.C.P. Edin.

A FINE record of public service ended with the death of Dr. William Galbraith, of Gosforth, Newcastle, on Jan. 6th, at the age of 87. Born at Ayr and educated at Ayr Academy, he qualified at Edinburgh in 1878. For 50 years he was in practice at Gosforth, and during that time held the appointments of medical officer of health, police surgeon, and public vaccinator. In this half century he initiated many public health improvements which were reflected in a decreasing death-rate, so much so that Gosforth was locally known as a health resort. As a physician he had a high reputation among his fellow practitioners as a quiet and remarkably correct diagnostician. He was a founder and the oldest member of the Gosforth Medical Association. A friend writes that "he was the true type of the ideal family doctor; to him the interests of his patients and profession were first and the business side last, frequently to his own personal loss. Naturally he was beloved and honoured by all of his patients, for whom he always had a cheery word; his healthy physique and smiling, ruddy face gave a cheering stimulus to everyone. His long life was fully occupied by his work and his sport—for he was more than usually an all-round sportsman. As a young man he was a good footballer and cricketer; for many years he was a member of the Northumberland cricket club and the city golf club. His prowess at bowls was noteworthy, and he toured many parts of Britain with local teams playing tournaments. His annual holiday was spent in shooting and fishing in Scotland." Dr. Galbraith is survived by two daughters. Dr. Nicol Galbraith, medical officer of health for South West Kent, is his nephew.

THE LATE MR. CECIL BEADLES

Prof. G. Grey Turner writes: "Cecil Beadles was a wonderful fellow, though his accomplishments were only known to a comparatively small circle. For the past few years he demonstrated to me the new specimens which had been added to the College museum during the previous year—the annual show, as he called it. He knew every specimen and every detail of the history available and was always ready to add to the interest of our talk by referring to other specimens in the museum, or by deploring the lack of something he sorely wanted. His anxiety to add to the collection in spite of his failing health gives something of the Hunterian ring to the last letter I had from him.

"'I enjoyed going round the show with you,' he wrote, 'and am always pleased to see the interest you take in it. Have you any specimens you think of presenting for next year? If so, I should be glad to have them as soon as possible, as I want to push on as much as possible during the next month or two. *I fear being laid up in the winter months.* I already have a fair number in preparation for 1933: some quite good things. Amongst these are some gall-bladders from Cairns Forsyth, a finger with radium carcinoma from Cuthbert Wallace, a heart with extraordinary dilatation of coronary vein—but I won't anticipate further. By the by, have you any specimens of sarcoma of bowel you can give us? we are badly off for these.'

"In preparation work Beadles was truly a marvel, and the way he could decide exactly how to cut a specimen in order to bring out its best features was almost uncanny. Nowhere in the world can better specimens be found than those prepared and mounted by his own hands. But he was not only a morbid anatomist, for he always corrected his observations by microscopical investigation, and had very clear views on pathological problems in general."

MEDICAL NEWS

University of Cambridge

DIPLOMA in MEDICAL RADIOLOGY AND ELECTROLOGY

The committee for medical radiology and electrology have approved the theses of the following candidates:—

Margaret A. Bromhall, J. S. Brown, G. T. Calthrop, E. N. Cook, E. R. Crisp, A. C. Devaraj, Nathaniel Fram, M. H. Hellman, R. F. Innes, J. N. Jacobson, S. A. Nagga, J. J. O'Grady, R. N. Perrott, F. G. Stewart, and E. R. Williams.

At recent examinations the following were successful:—

Part I.—J. S. Austin, L. R. B. Birt, L. G. Blair, Isedor Fine, F. C. Golding, Elizabeth M. Haworth, Robert McWhirter, W. W. Main, R. F. May, R. J. L. O'Donoghue, R. M. Patterson, R. F. Phillips, E. J. Rawnsley, William Sowerby, Elizabeth M. F. Taylor, A. R. Thomas, J. Z. Walker, and B. W. Windeyer.

National University of Ireland

University College, Cork.—At recent examinations the following candidates were successful:—

M.D.

Myles McSwiney.

M.B., B.CH., AND B.A.O.

Charles Delea and J. J. O'Sullivan.

Royal College of Surgeons of England

A quarterly meeting of the council was held on Jan. 12th, with Sir Holburt Waring, the president, in the chair. Resolutions of condolence were passed on the death of Mr. H. S. Clogg, chairman of the court of examiners, and of Mr. C. F. Beadles, pathological curator of the museum.

Diplomas were granted, jointly with the Royal College of Physicians, as follows:—

Public Health.—S N. Bandyopadhya, W. D. T. Brunyate, Alice E. N. Gilby, A. W. Johns, Stephen Knight, Mohan Singh, M. M. Syddiq, L. D. Williams, and H. M. Willoughby.

Tropical Medicine and Hygiene.—Mabel G. Brodie, D. D. Karunaratna, C. K. Lakshmanan, and V. Nadarajah.

Psychological Medicine.—Sophia Antonovitch, G. G. Brown, Samuel Carden, H. W. D. Crook, J. L. Faull, B. M. C. Gilsenan, Kenneth Hazell, J. K. C. Liddell, J. R. Murray, F. E. North, T. P. Parr, Norman Rawstron, G. M. Smith, and G. V. Stephenson.

Laryngology and Otology.—Robert Evans, Leonard Jacobson, Joshua Mazell, H. C. Meathrel, K. V. B. Pillai, A. F. Quark, Aaron Rakoff, Arnold Rose, B. K. Sheorey, M. R. Sheridan, and I. B. Thorburn.

Medical Radiology.—A. A. Digges la Touche and G. D. Stever

Sir Cuthbert Wallace was appointed Hunterian orator for 1934. Mr. T. W. P. Lawrence was appointed acting pathological curator. Prof. R. E. Kelly was re-elected a member of the court of the University of Liverpool for the ensuing three years. The Hallett prize for anatomy and physiology was awarded to Mr. S. G. Nardell, of King's College, London.

Forthcoming lectures.—The following lectures will be given on Mondays, Wednesdays, and Fridays during January and February: Jan. 23rd, Mr. Arthur Edmunds on unsuccessful appendicectomy; Jan. 25th, Mr. Harold Burrows on the induction of cancer in animals by pure chemical substances; Jan. 27th, Mr. W. E. M. Wardill on the principles of treatment of cleft palate; Jan. 30th, Mr. Kenneth Walker on per-urethral operations on the prostate; Feb. 1st, Mr. P. H. Mitchiner on the treatment of burns and scalds, with special reference to the use of tannic acid; Feb. 3rd, Mr. J. Paterson Ross on sympathectomy as an experiment in human physiology; Feb. 6th, Mr. H. P. Winsbury-White on the paths of infection between the genital organs and the urinary tract; Feb. 8th, Mr. Stanford Cade on radiation treatment of cancer of the mouth and pharynx; Feb. 10th, Mr. H. Jackson Burrows on tissue culture in its relationship to surgical pathology; Feb. 13th, Mr. P. N. B. Odgers on the anatomy of the lumbar and lumbo-sacral diarthroidal joints in man; Feb. 15th, Prof. R. J. S. McDowall on experimental shock, with special reference to anæsthesia; Feb. 17th, Mr. R. W. Raven on diverticula of the pharynx and œsophagus, with special reference to the morphological and embryological aspects; Feb. 20th, Mr. Laurence O'Shaughnessy on thoracic surgery—the factor of post-operative infection; Feb. 22nd, Mr. G. A. Mason on the surgical significance of the vitelline duct; Feb. 24th, Mr. E. R. Flint on pre-operative procedure. All the lectures will be given at the College at 5 P.M.

University of London

Six lectures on the Physiology of the Nervous System in Man will be given at the Middlesex Hospital medical school, Mortimer-street, W., by Prof. Samson Wright, at 5 P.M. on Tuesdays and Thursdays from Feb. 7th to 23rd inclusive. No tickets are required.

At a meeting of the court on Jan. 11th, with Lord Macmillan, the chairman, presiding, it was announced that the Clothworkers' Company, the Grocers' Company, the Drapers' Company, and the Skinners' Company had each decided to make grants to the university in the shape of annual payments extending over a series of years. These grants will amount in all to £20,000 from the Clothworkers' Company, £10,000 from the Grocers' Company, £5000 from the Drapers' Company, and £5000 from the Skinners' Company. Like the grants already announced from the corporation of the City of London, from the Mercers' Company and from the Fishmongers' Company, these benefactions will be applied towards meeting the cost of the new ceremonial hall to be erected on the university's site in Bloomsbury.

Society for Relief of Widows and Orphans of Medical Men

At a quarterly court of directors held on Jan. 4th, Dr. W. Culver James, the senior Vice-President, being in the chair, grants amounting to £1975 were voted for the half-yearly payments to the widows and orphans in receipt of relief. Of this amount, £112 10*s*. was for special grants to orphans to enable them to continue their education, or assist them in embarking on careers. The expenses of the quarter were £88 2*s*. 6*d*. In December last £640 was distributed as a Christmas present. There are now 52 widows and seven orphans in receipt of relief. Six new members were elected at the meeting, and two resignations were accepted. Membership is open to any registered medical practitioner who at the time of his election is residing within a 20-mile radius of Charing Cross. Application forms from the secretary of the society at 11, Chandos-street, London, W.1.

Fellowship of Medicine and Post-Graduate Medical Association

Arrangements for next week will be found in our Medical Diary. A course in Dermatology will be given at St. John's Hospital from Jan. 30th to Feb. 25th, which will include clinical instruction daily, and lectures on Tuesdays and Thursdays. There will also be a course in gynæcology at the Chelsea Hospital from Feb. 6th to 18th (either morning or afternoon sessions may be attended); an all-day course in diseases of the chest at the Brompton Hospital from Feb. 6th to 11th; a course in antenatal treatment at the Royal Free Hospital from Feb. 3rd to March 11th on Fridays at 5 P.M.; and a week-end course in physical medicine at the London Clinic and Institute of Physical Medicine on Saturday, Feb. 11th, and Sunday the 12th. Courses, lectures, and demonstrations are open only to members and associates of the Fellowship of Medicine, and further particulars may be had from the secretary of the Fellowship at 1, Wimpole-street, London, W.1.

Sir James Dundas-Grant has been elected an honorary member of the Italian Society of Laryngology, Otology and Rhinology.

Royal Aeronautical Society

On Thursday, Jan. 26th, at 6.30 P.M., Wing-Commander G. S. Marshall, M.R.C.S., is addressing this society on The Physiological Limitations of Flying. The lecture will be given in the hall of the Royal Society of Arts, 18, John-street, Adelphi, London, W.C.

Post-Graduate Work in Newcastle

Four special courses have been arranged for the months of January, February, and March by the University of Durham. On Wednesdays at 4 P.M., beginning on Feb. 8th, there will be weekly lectures on diseases of infancy and childhood, either in the Babies' Hospital or in the Royal Victoria Infirmary, Newcastle. It is proposed that the course on diseases of the eye should meet at the Royal Victoria Infirmary on Mondays, beginning on Jan. 23rd, at 12.0 noon, but the time may be altered by agreement. Ten meetings will be held dealing with infectious diseases and tuberculosis at the City Hospital, Walker Gate, on Thursdays at 3.30 P.M., commencing on Jan. 19th. From Tuesday, Jan. 24th, there will be ten weekly demonstrations at 3 P.M. on diseases of the skin at the Royal Victoria Infirmary. Fees are charged for these courses, and application should be made to the registrar of the College of Medicine, Newcastle. Classes for clinical instruction in medicine and surgery will be held every Sunday morning at 10.30 from Jan. 22nd to March 26th, at the Newcastle General Hospital.

Grants in Aid of Scientific Research

The Council of the British Medical Association announces that it is prepared to receive applications for research scholarships as follows: an Ernest Hart memorial scholarship, of the value of £200 per annum; a Walter Dixon scholarship, of the value of £200 per annum; and three research scholarships, each of the value of £150 per annum. These scholarships are given to candidates whom the Science Committee of the Association recommends as qualified to undertake research in any subject (including state medicine) relating to the causation, prevention, or treatment of disease. Each scholarship is tenable for one year, commencing on Oct. 1st, 1933. A scholar may be reappointed for not more than two additional terms, and is not necessarily required to devote the whole of his or her time to the work of research, but may hold university or other appointments, provided the duties do not interfere with his work.—Grants: The Council of the Association is also prepared to receive applications for grants for the assistance of research into the causation, treatment, or prevention of disease, when preference will be given to applicants who propose as subjects of investigation problems directly related to practical medicine. Applications for these scholarships and grants must be made not later than Saturday, May 20th, 1933, on a form, supplied on application to the Medical Secretary of the Association, B.M.A. House, Tavistock-square, London, W.C.1. They must be accompanied by the names of three referees, competent to speak as to the capacity of the applicant for the researches proposed.

Medical Society of Individual Psychology

The annual dinner of this society was held on Jan. 12th at the Florence Restaurant, London, with Prof. W. Langdon Brown, the chairman, presiding. Dr. F. G. Crookshank, the hon. secretary, announced the result of elections for membership and associateship, bringing the list to 97, and the chairman, commenting on the increase from 9 in 1930 to 97 in 1933, proposed the election of Drs. Zilahi, Seif, and Alfred Adler as honorary members. This was carried with acclamation, and Prof. Langdon Brown, announcing the completion of the "century," suggested that Dr. Adler should be invited to become honorary president of the society. He then proceeded to give the toast of the society, remarking that sound critics had declared the outstanding medical event of 1932 to have been the progress made in the recognition of psychology as an integral part of medicine and a necessity to the study of the individual patient. This advance, he declared, was in great measure due to the work of the society. Dr. O. H. Woodcock gave the health of the guests, including Dr. Henry Devine, president of the section of psychiatry of the Royal Society of Medicine, and Dr. Graham Howe, president of the medical section of the British Psychological Society. Dr. Devine replied in a speech, emphasising the links between general medicine and psychology and psychiatry. Dr. Crookshank proposed the health of the chairman in terms expressive of the great gratitude felt by every member of the society for the invaluable help, guidance, and support afforded them by him during the last two years. Prof. Langdon Brown, in reply, declared his confidence in the assured future of the work of the society.

remuneration. One of these curative workshops, where physical and occupational therapy are used for industrial accident cases, received some $8000 in 1920 from insurance companies in payment for treatment of cases. Insurance companies would be unlikely to expend this money unless they were satisfied that the time for payment of compensation was thereby reduced.

The organisation of these workshops varies a little. One in Rochester, N.Y., receives all types of cases. Patients are referred to it by hospital clinics, by various social and relief agencies, and by private physicians.

> All patients go to the occupational therapy department on admission and from there those requiring special training are passed on to the industrial therapy department where they receive a hardening process until they are capable of full-time employment. The work is done under normal industrial conditions under an experienced foreman. Payment is made on a piece-rate basis but is very small and is in no way a substitute for compensation. Cases of tuberculosis, heart disease, psychoses, neuroses, post-operative and orthopædic conditions are all treated in this workshop which has proved to be self-supporting and reports a return of about 64 per cent. of the patients treated to full-time work. Another shop gives free treatment in the shop and at home to cases unable owing to their illness to attend the shop, and charges $1 for patients outside the city and gives instruction to non-patients for $1 per lesson. Each patient must bring a card from his doctor stating what sort of work he is capable of and how much he may do each day. The shop pays for the materials and the patient is paid for work when it is sold. Workers may keep their own work by paying for the material and a small extra charge to cover overhead expenses. About 135 patients are treated in this workshop.

Some private clinics have also been opened by trained occupational therapists. In them no cases are received without a medical prescription. One such clinic reports special success with cases of infantile paralysis sent for functional restoration, and also several cases where, owing to some permanent disability following accidents, patients have been trained in some new craft which enables them again to earn their own living—for example, a chauffeur who had become blind, became an efficient rug-maker; and a blacksmith who was taught a specialised form of wrought-iron work became so proficient at it that his former employer fitted up a workshop for him in his own home and kept him permanently supplied with work.

Perhaps most of all in the case of tuberculous patients do these industrial workshops meet an important need, and for this particular group of patients colonies or centres have been established in other countries, as for example at Papworth Hall, in England, and by the Italian Red Cross at Al Cuasso Al Monte, in Italy.

In Mental Hospitals

It is probably in mental hospitals that the greatest scope for occupational therapy is found. The patients who enter these hospitals fall into two groups: first, those who may recover; and secondly, the chronic cases who will in all probability spend the rest of their lives in hospital. The occupational therapy department is concerned with them all. The aim of those in charge of these patients is to help them to readjust themselves to life and to guide them back to a useful life in the outside world or in the hospital community.

Taking as its aim the making of each patient into a socially useful member of the community, occupational therapy in a mental hospital includes: (1) therapeutic work which is prescribed as a definite part of treatment, and with the intention of improving the patient's mental state; and (2) non-therapeutic work among chronic cases which is none the less valuable in that it keeps the patients healthy and as near normality as is possible for them, and because it makes possible the carrying on of the work of the hospital and enables those who would otherwise be a burden on the community to contribute in some measure to the cost of their maintenance. In this class are found the imbeciles, the feeble-minded, the secondary dementias, and a number of dementia præcox cases, all of whom are capable of good work under supervision. Though these patients are not likely to improve they should be kept occupied, first, because occupation of some kind is necessary to a normal life and they will be much happier and healthier if useful members of the hospital community; secondly, because, as is constantly being proved in the wards of a mental hospital, "Satan finds work for idle hands to do"; thirdly, as a duty to society; and lastly, because occupation retards regression and dementia.

One aims, of course, at employing all these patients in the hospital industries; a few can be sent there immediately on admission but the majority cannot, and it is for this reason that a properly organised occupational therapy department, with different grades as it were, is of value. Such a department will include provision for the employment of patients on admission. This may be in bed, in a ward occupational therapy class, or in the work of the ward. In this grade the work is therapeutic; the patients are under constant individual supervision, and the work should be carefully and deliberately prescribed with the intention of helping them towards recovery, or with the purpose of training them to become useful hospital workers. From this grade the patients are passed on—the possible recoveries to larger occupational therapy centres, for example, a sewing-room or weaving or handicrafts room, where they will receive less individual attention but will still be under the constant supervision and guidance of an instructor who will understand their mental state and endeavour to select the form of occupation that is most likely to benefit them, and they should spend part of each day in one or other of these classes until discharged from the hospital. The chronic cases are passed on to the hospital industries: laundry, sewing-room, tailor's and carpenter's shops, &c. Experience has shown that chronic cases who have been sent to the workshops shortly after admission have frequently been returned to the ward as unfit, but the same patients, after some weeks' training in a small centre, get into the way of regular occupation and when sent again prove to be useful workers.

Many chronic cases, of course, cannot be sent to the workshops; some of these can be taught to work in the wards but others, either because their mental state remains too acute—they are too noisy, destructive, restless, agitated, liable to impulsive outbursts—or because they remain incapable of attending to themselves in any way without constant stimulation. Such patients drift into the acute or "refractory" or the "lost" wards of the hospital, and until recently their condition has been regarded as hopeless. Handicraft classes, however, when started in the "refractory" wards have shown that a large number of these patients can be taught to occupy themselves usefully for long periods each day. The type of work given to them is necessarily limited as nothing requiring tools with which they might injure themselves or others may be introduced into such wards, but rug-making; certain kinds of weaving, needlework, basketry, and the preparation of old "useless" material—i.e., unravelling of old stockings, tearing into strips of old materials for rug-making, &c.—will provide an adequate variety of occupation which, besides being useful, will keep such patients employed and out of mischief and introduce into the ward an atmosphere of quiet and industry in place of one of quarrelling, noise, and strife.

HABIT-TRAINING CENTRE

For the treatment of the "lost" patients, the majority of whom belong to the dementia præcox group, the habit-training centre has been introduced. These patients have gradually lost interest in the external world, till finally they have ceased to take any interest in anything outside the world of phantasy in which they live. They are completely indifferent with regard to their personal appearance and many reach the stage where they are faulty in habits and will neither wash, dress, nor feed themselves. Superficially there is no apparent difference between these "lost" patients and those cases of secondary dementia who have reached a similar stage, but there is this difference, that whereas in the latter, though the progress of dementia may sometimes be retarded for a time, they do not improve; among the dementia præcox cases from time to time patients do improve, and when they improve they show very little sign of mental deterioration. It is also found that when one has time to persevere with individual patients and make them attend to what one wants them to do, they can do it perfectly well.

They have regressed to a state similar to that of babyhood where everything is done for them, where they have no responsibilities of any kind, and where their mind is occupied in a world of its own. Habit-training is necessary in a child to teach him to control his own body and to adapt himself to his surroundings. Physical control he learns by developing regular habits, emotional control through his work and play with others. The foundation of a habit depends upon repetition and upon never allowing an exception, and it is very little use to make a patient clean his teeth or button his shoes, or tidy his hair one day then leave him for a week, then start teaching him again. The chief value of the habit-training centre lies in the fact that every patient is supervised and trained every day until new and correct habits are formed. A definite schedule is followed from the moment the patients get up in the morning till the moment they go to bed and, where necessary, during the night. It is arranged as far as possible so that the patient leads a normal life and includes work, exercise, and play.

The following programme[*] is adopted in the habit-training centres of the New York State mental hospitals:—

A.M.—6: Rising bell. 6 to 7: Wash, brush teeth use mouth wash, dress, lace shoes, comb hair, air beds properly. 7 to 7.30: Breakfast. 7.30 to 8.30: Train patients to make beds, sweep floors, and general care of wards. 8.30 to 8.45: Prepare for physical exercise. 8.45 to 9.30: Marching, free hand calisthenic work. All windows open, or exercise carried on out of doors. Pass water. 9.30 to 11: Assigned occupational work, except with certain groups when the time is limited by the physician. 11 to 11.30: Water, make person tidy for dinner. 11.30 to 12: Line up to roll call for dinner.

P.M.—12 to 12.30: Dinner. 12.30 to 1.30: Absolute rest. 1.30 to 2: Pass water, prepare for occupational treatment (brush hair, wash hands). 2 to 3.45: Assigned occupational work. 3.45 to 4.30: Walk out of doors three-quarters of an hour. 4.30 to 5: Water, make person tidy for supper. 5 to 5.30: Supper. 5.30 to 7.30: Comfortable on ward, reading, games under direction, singing if possible. 7.30 to 8: Wash, brush teeth, ready for bed. Bed-wetters should be taken to toilet at regular intervals during the night; at 10 P.M., 2 and 6 A.M.

Occupational therapy in this ward consists of unravelling and winding, rug-making, weaving on frames, raffia and basketry work, brush-making, and needlework.

The habit-training centre consists of 25 patients, 3 nurses, and an occupational therapist.

One hospital started a ward of this kind in 1927 with 12 patients and the results of the treatment have been such that they now have five classes, the ward consisting of 70 instead of 12 patients, and they are hoping to organise classes for another 70 in the near future. Of the 70 who have received treatment at the centre they report that instead of 70 patients requiring handfeeding, 21 now do; instead of 30 requiring dressing, 3 now do. There has been marked improvement in 20 per cent. of the cases, moderate improvement in 10 per cent., and no change in 10 per cent. Another hospital reports that of 75 cases treated, 12 improved sufficiently to be sent home on trial, 13 to be sent to the hospital industries, and 24 to be sent to better wards where individual attention was not considered necessary.

All the cases treated have been of the lost, deteriorated type; better results are naturally obtained with early cases than with those in whom bad habits have existed for years, and the cases treated in the habit-training centres up to date have been definitely selected. They must (1) be under 35 years of age; (2) not have been more than 15 years in a mental hospital; (3) have been of fair mental development before the onset of their illness.

The amount of help that a patient may obtain from occupational therapy depends in a very large measure upon the occupational therapist, upon her tact, sympathy, and power of understanding the patient's mental state and individual needs. In most cases any employment is better than none, but work selected for each individual patient with his or her particular needs in view is likely to help them far more than work given to them haphazard. For example, if a patient is given work that she is mentally incapable of doing satisfactorily she will become depressed, her lack of self-confidence may be increased, she will lose interest, and probably give it up. On the other hand, if an intelligent patient is given something mechanical that requires very little concentration, she will do it mechanically and will occupy herself during the whole period of the class, but the therapeutic value of the work will probably be practically nil. The purpose of the occupation is to engage the patient's mind so that while she is at work the sense of depression or the delusions from which she suffers, or the hallucinations which distress her when her attention is not otherwise held, are driven out.

This is illustrated in the case of a restless patient suffering from distressing auditory hallucinations who was sent to the occupational therapy department shortly after her admission to the hospital. She was put to work at rug-making on a loom. The work was new to her and occupied all her attention. She said that while she was busy she did not "hear the voices," looked forward to the class and improved generally for about a fortnight. Then she became restless and anxious again and her work no longer helped her. She had been working on a plain rug and it was found that she could now do the work quite mechanically without paying much attention to it; she was moved to another rug in which a complicated pattern was being introduced which required her full attention and again she improved. The patient herself noticed what happened and next time asked for a change of occupation.

It must be remembered, however, that work in the occupational therapy class is not necessarily the best treatment for all patients; some will improve more rapidly as ward-workers.

For example one overactive patient who was rather resentful of her detention in hospital, on being asked at the end of a couple of weeks how she was getting on in the handicrafts class, shrugged her shoulders and said, "Oh, you mean the kindergarten class, waste of time!" She was handed over to the charge nurse who employed her in the ward where she settled down and became much happier and more amenable to treatment.

On the other hand many patients, if given mending or ward work to do will become resentful and say that if they can do that kind of thing in hospital they could be doing it at home, that they did not come to work, &c. It is for the occupational therapist to discover the particular need of each patient, and it will thus be realised how important it is to have trained workers.

Training for Occupational Therapy

In this country there has been until quite recently no recognised training centre for the occupational therapist. The work has been done in some hospitals by nurses who, after taking their nursing certificate, learn some handicrafts and then take on the work of occupational therapist; others have had no medical training, but have a technical knowledge of certain crafts; both learn gradually by experience how to make their work of therapeutic value and not simply a form of employment. In the United States there are a number of recognised training schools, the students of which, when they have completed their remuneration. One of these curative workshops, where physical and occupational therapy are used for industrial accident cases, received some $8000 in 1920 from insurance companies in payment for treatment of cases. Insurance companies would be unlikely to expend this money unless they were satisfied that the time for payment of compensation was thereby reduced.

The organisation of these workshops varies a little. One in Rochester, N.Y., receives all types of cases. Patients are referred to it by hospital clinics, by various social and relief agencies, and by private physicians.

> All patients go to the occupational therapy department on admission and from there those requiring special training are passed on to the industrial therapy department where they receive a hardening process until they are capable of full-time employment. The work is done under normal industrial conditions under an experienced foreman. Payment is made on a piece-rate basis but is very small and is in no way a substitute for compensation. Cases of tuberculosis, heart disease, psychoses, neuroses, post-operative and orthopædic conditions are all treated in this workshop which has proved to be self-supporting and reports a return of about 64 per cent. of the patients treated to full-time work. Another shop gives free treatment in the shop and at home to cases unable owing to their illness to attend the shop, and charges $1 for patients outside the city and gives instruction to non-patients for $1 per lesson. Each patient must bring a card from his doctor stating what sort of work he is capable of and how much he may do each day. The shop pays for the materials and the patient is paid for work when it is sold. Workers may keep their own work by paying for the material and a small extra charge to cover overhead expenses. About 135 patients are treated in this workshop.

Some private clinics have also been opened by trained occupational therapists. In them no cases are received without a medical prescription. One such clinic reports special success with cases of infantile paralysis sent for functional restoration, and also several cases where, owing to some permanent disability following accidents, patients have been trained in some new craft which enables them again to earn their own living—for example, a chauffeur who had become blind, became an efficient rug-maker; and a blacksmith who was taught a specialised form of wrought-iron work became so proficient at it that his former employer fitted up a workshop for him in his own home and kept him permanently supplied with work.

Perhaps most of all in the case of tuberculous patients do these industrial workshops meet an important need, and for this particular group of patients colonies or centres have been established in other countries, as for example at Papworth Hall, in England, and by the Italian Red Cross at Al Cuasso Al Monte, in Italy.

In Mental Hospitals

It is probably in mental hospitals that the greatest scope for occupational therapy is found. The patients who enter these hospitals fall into two groups: first, those who may recover; and secondly, the chronic cases who will in all probability spend the rest of their lives in hospital. The occupational therapy department is concerned with them all. The aim of those in charge of these patients is to help them to readjust themselves to life and to guide them back to a useful life in the outside world or in the hospital community.

Taking as its aim the making of each patient into a socially useful member of the community, occupational therapy in a mental hospital includes: (1) therapeutic work which is prescribed as a definite part of treatment, and with the intention of improving the patient's mental state; and (2) non-therapeutic work among chronic cases which is none the less valuable in that it keeps the patients healthy and as near normality as is possible for them, and because it makes possible the carrying on of the work of the hospital and enables those who would otherwise be a burden on the community to contribute in some measure to the cost of their maintenance. In this class are found the imbeciles, the feeble-minded, the secondary dementias, and a number of dementia præcox cases, all of whom are capable of good work under supervision. Though these patients are not likely to improve they should be kept occupied, first, because occupation of some kind is necessary to a normal life and they will be much happier and healthier if useful members of the hospital community; secondly, because, as is constantly being proved in the wards of a mental hospital, "Satan finds work for idle hands to do"; thirdly, as a duty to society; and lastly, because occupation retards regression and dementia.

One aims, of course, at employing all these patients in the hospital industries; a few can be sent there *immediately on admission but the majority* cannot, and it is for this reason that a properly organised occupational therapy department, with different grades as it were, is of value. Such a department will include provision for the employment of patients on admission. This may be in bed, in a ward occupational therapy class, or in the work of the ward. In this grade the work is therapeutic; the patients are under constant individual supervision, and the work should be carefully and deliberately prescribed with the intention of helping them towards recovery, or with the purpose of training them to become useful hospital workers. From this grade the patients are passed on—the possible recoveries to larger occupa*tional therapy centres, for example, a* sewing-room or weaving or handicrafts room, where they will receive less individual attention but will still be under the constant supervision and guidance of an instructor who will understand their mental state and endeavour to select the form of occupation that is most likely to benefit them, and they should spend part of each day in one or other of these classes until discharged from the hospital. The chronic cases are passed on to the hospital industries: laundry, sewing-room, tailor's and carpenter's shops, &c. Experience has shown that chronic cases who have been sent to the workshops shortly after admission have frequently been returned to the ward as unfit, but the *same patients, after some weeks' training* in a small centre, get into the way of regular occupation and when sent again prove to be useful workers.

Many chronic cases, of course, cannot be sent to the workshops; some of these can be taught to work in the wards but others, either because their mental state remains too acute—they are too noisy, destructive, restless, agitated, liable to impulsive outbursts—or because they remain incapable of attending to themselves in any way without constant stimul[illegible] Such patients drift into the acute or "refractor[illegible] or the "lost" wards of the hospital, and until recently their condition has been regarded as hopeless. Handicraft classes, however, when started in the "refractory" *wards have shown that a large* number of these patients can be taught to occupy themselves usefully for long periods each day. The type of work given to them is necessarily limited as nothing requiring tools with which they might injure themselves or others may be introduced into such wards, but rug-making; certain kinds of weaving, needlework, basketry, and the preparation of old "useless" material—i.e., unravelling of old stockings, tearing into strips of old materials for rug-making, &c.—will provide an adequate variety of occupation which, besides being useful, will keep such patients employed and out of mischief and introduce into the ward an atmosphere of quiet and industry in place of on of quarrelling, noise, and strife.

HABIT-TRAINING CENTRE

For the treatment of the "lost" patients, the majority of whom belong to the dementia præcox group, the habit-training centre has been introduced. These patients have gradually lost interest in the external world, till finally they have ceased to take any interest in anything outside the world of phantasy some singing on the wireless, screamed " Oh, those awful voices again," and relapsed into a state of acute agitation. But these cases are exceptional.

The need that is felt for occupation and self-expression in some form by most individuals is llustrated if one walks through the wards of a mental hospital in which no form of occupation is provided. Patients are to be seen attempting to provide it for themselves, some may be seen knitting on hairpins, unravelled stockings being used for wool; odd things being made with ingenious tools they have created for themselves, sometimes beautiful embroidery is being done on old scraps of material. Some time ago an exhibition was held at a mental hospital in the United States of this kind of work done by patients in the hospital. Some of the exhibits had been created simply for the pleasure of producing something beautiful or useful; others, however, were of greater interest, for example, several complicated wood and metal machines one of which, the patient who made it claimed, controlled all the deliberations of the League of Nations, while another was said to regulate the movements of the universe and to direct the stars in their courses. The examination of this unguided occupation shows that what might be useful labour is being wasted, beautiful work often being done on worthless material; that great ingenuity is being used to no purpose, and in addition to this the work is often carrying the patient further into the world of phantasy and strengthening and emphasising delusions.

The occupation of the sick is still regarded by many as a diversion or amusement which will " take the man out of himself " for a short period and thus temporarily relieve his trouble, and this was no doubt the original purpose of those who attempted to employ their patients and it still serves this undoubtedly important purpose, but experience has shown those who have used it that it may be made to serve many other purposes and may, if prescribed and applied scientifically, prove a valuable form of therapy instead of an amusement which may or may not benefit the patient. It must be always remembered that occupational therapy is only a part of general therapy. It does not cure, nor does it claim to do so, but it does assist and hasten cure.

A CHILD GUIDANCE CONFERENCE

THE staffs of all the clinics in Great Britain organised on child guidance lines met in conference on Jan. 7th–8th in London, with Dr. William Moodie as president. After the first two sessions, the psychiatrists, psychologists, and social workers met separately under the chairmanship of Dr. Emanuel Miller, Dr. Lucie Fildes, and Miss Doris Robinson, respectively, who reported to a final meeting upon the general findings of the three sections.

The psychiatrists discussed the status of the social worker in relation to the psychiatrist and the families being investigated. While the social worker was trained to take a detached view of the field she was investigating, there was some danger, it was felt, of her establishing such emotional relationships with the family that the work of the psychiatrist might thereby be handicapped. While the value of the unity of psychiatrist, social worker, and psychologist was recognised, it was felt that a clinic was most successful where the physician maintained his authority in directing the social worker; in making suggestions as to approach; and deciding at case conferences where the future treatment of the child should lie—that is, in the psychiatric, the social, or the psychological field. The open case conference on a half-developed case was apt to misrepresent to casual visitors the work of child guidance. The investigation of play, both group and individual, was regarded as of first importance for diagnosis and cure in any clinic. Much could be gleaned of a child's social behaviour, intelligence, and emotional reactions from these observations, but it was premature to base their interpretation on current theories. The value of personality tests was considered, particularly the use of the Rohrschach tests; it was felt that discoveries could often be made on purely clinical lines without the use of time-devouring tests.

The social workers' group discussed means of organising their work under methods of treatment varying according to the views of the psychiatrist with whom they work. In small clinics where medical staff is part-time only, much responsibility for adjustment falls upon the social worker. Emphasis was laid on the need, when treating behaviour problems, of knowing working-class living conditions and standards, and of basing plans upon the real possibilities for adjustment.

In the psychological section discussion on clinical diagnosis and treatment developed the following points. Individual free play is recognised as a method of observation and as of probable therapeutic value: in certain selected cases more organised social and constructive play activity may be a profitable line of treatment. Control groups are necessary for the provision of data bearing on the value of treatment; though difficult, this method of evaluation is not impossible. The most hopeful line of growth of personality tests appears to be in the discovery of group factors underlying certain types of behaviour. While work in these directions has already given profitable results, much more experiment is needed before they can be used clinically.

The conference was held at the Institute of Medical Psychology under the auspices of the Child Guidance Council of Great Britain.

NURSING HOMES

Two small books recently issued provide between them probably as much information about nursing homes in this country as can be made available without infringing laws, written and unwritten. What a doctor really wants to know about a home is whether the accommodation and food is good for the price charged; whether the amount of actual nursing provided, and personal attention, day and night without extra charge for a " special," is at least up to the somewhat low standard customary in such institutions; whether there is a lift; whether the patient's bell is answered promptly; whether trained nurses only are employed; and many other things of this kind. This information is, however, unobtainable, except through personal experience; incidentally, a record of impressions of any particular home mentioned would soon make a directory of names and addresses a very useful document to its owner and his patients. Nursing Homes, 1933,[1] provides a list of registered nursing homes in England and Wales, Scotland, and Ireland, arranged according to counties and towns, with full address and telephone number, and a note whether medical, surgical, maternity, or only convalescent cases are accepted. Where, as sometimes occurs, more particulars are available among the advertisement pages, a reference to the appropriate page is also given; but even there the weekly terms are not always stated. London nursing homes are classified under postal districts. The book also contains a short list of mental homes, no indication being given whether certified or uncertified, or both types of cases are accepted. In the advertisement pages are set out trained nurses' institutes, hotels, and guest houses, a scholastic and training, may become registered as occupational therapists.

Historical Review

The idea that occupation is therapeutic and beneficial to the sick is by no means a new one. As long ago as A.D. 172 Galen wrote "Employment is nature's best physician." In 1798 Dr. Rush, of Philadelphia, prescribed "spinning, sewing, and churning" for his women patients in a mental hospital in Philadelphia; "grinding corn, gardening, and cutting corn" for the men. Again, about 1815 we find the therapeutic value of occupation in a mental hospital being discussed in a correspondence between a physician of the York Retreat and one of the founders of a hospital for the insane in New York. In it we hear that one of the leading features of the new hospital is to be the introduction of employment for the patients; and that in a hospital in Spain which received patients of all ranks the proportion of recoveries among the lower classes, who were employed in the work of the hospital, was much greater than that among the idle grandees. But up to the time of the Great War, in most hospitals little was found in the way of occupation apart from the hospital industries. Successful work was being done here and there by a few individuals who were attempting not simply to occupy and amuse patients, but to treat them through occupation, and it was their success with isolated cases that led the authorities in various hospitals to consider the training of workers definitely for this purpose, for it was seen that if the full possibilities of the work were to be realised the workers must have some definite training. First, they must have in the case of workers with orthopædic and surgical cases a knowledge of anatomy, in the case of workers with mental patients a knowledge of psychology and mental diseases; secondly, they must have a practical knowledge of suitable handicrafts; and thirdly, they must understand how to apply those handicrafts to meet the need of each individual patient.

The first school of occupational therapy was founded in Chicago and was the only one up to the time of the war, when far more trained workers were demanded from it than it could supply. After the war, in 1920, the American Association of Occupational Therapists fixed a standard of training and stated the minimum requirements. These now include:—

1. A certain standard of intelligence and education for admission to the course.
2. A minimum course of 12 months of which not less than eight shall be spent in practical instruction in handicrafts and lectures.
3. Not less than six months (in some schools it is nine) of practical training in a hospital under a trained occupational therapist.

Each student thus, before commencing work independently, acquires a thorough training in theory and technique, and has had some months' actual experience, during which she has had the opportunity of working under an experienced person and of observing all the little details which will add to the value of her class.

In the arrangement of her room she will learn to use separate small tables for patients who tend to be more interested in other people's work than their own and irritate and interfere with others (manias), or for certain melancholias who like to recount all their troubles to their friends—though certain patients are stimulated by their neighbours. She will observe that confused patients who cannot concentrate sufficiently to understand verbal instruction may sometimes be taught to do simple things by guiding their hands—that the dull, mechanical work, cutting wool, stitching braid, &c., which is necessary to provide the department with materials, but which would fail to arouse any interest in the majority of patients, can be satisfactorily done by the senile dementias, and many other details.

Finance

Apart from the salaries of the occupational therapists it is possible for an occupational therapy department to be self-supporting. Whether it is or not depends to a very great extent on the care and ingenuity of the occupational therapist. A certain quantity of new material and tools are essential, but an enormous amount may be done with the discarded and waste articles from other departments of the hospital.

Old clothes may be cut up and used for many purposes, condemned linen, sugar sacks, and old stockings dyed and cut up or unravelled provide material for rugs, weaving, and embroidery; old jam pots may be used for painting, tins for enamelling, &c. All these provide material for useful and saleable articles, and are but a few of the things which may be put to a good use that would otherwise be thrown away.

For the disposal of finished articles in some hospitals there is a permanent exhibition of completed work and patients, visitors, and staff may buy things whenever they wish. Other hospitals hold an annual sale for the public and allow staff and patients to purchase things throughout the year. It is, of course, up to the occupational therapist to see that useful and attractive things are produced in the department, partly because they will be more easily sold, but still more because the patients themselves will be more interested in making such things than in producing useless articles. It must, however, be clearly understood throughout the department that the commercial side must always be subsidiary to the therapeutic; that the purpose of the department is to heal the patient and never to make money; that if no article were sold the value of the work done would still be just the same, and no patient should ever be put to or kept at work which is not the most helpful to him or her simply to produce saleable goods.

In hospitals, where it is possible to employ a sufficient number of occupational therapists to organise the work on a large scale and attempt to occupy the majority of patients in the wards, the occupational therapist may replace a nurse for long periods each day; this, of course, is not possible where only small classes consisting of a few patients from a ward can be held. It must be remembered, however, that if through treatment in the occupational therapy department the length of a patient's stay in the hospital is diminished, this in itself results in a considerable saving in public expense.

Recreation

In some hospitals the occupational therapy department undertakes also the organisation of recreation and amusement. Recreation officers are attached to the department and regular programmes are followed which provide daily exercise, in the form of gymnastics, gardening, organised games, swimming, walks; and amusement in the form of concerts, singing classes, music, wireless, cinemas, dances, socials, for all patients. In other hospitals recreation and amusement are arranged independently. All are equally important and play their part in helping the patient to readjust to normal life. Many patients, who in the ward are difficult to manage, mischievous, impulsive, restless, and unable to settle to anything, will give no trouble whatever in a gymnastic or Morris dancing class, but will coöperate and work well. This helps them to redevelop their power of self-control and concentration. On more than one occasion patients who have remained dull, apathetic, and impossible to stimulate, have first shown signs of returning interest in external things during the Christmas parties which are held in all hospitals—this occurred on one occasion in the case of a stuporose dementia præcox who had remained two years in bed, *requiring every attention*, including washing and feeding.

Music, too, has an influence on many patients and may create a change of mood. Hostile patients may become friendly, and solitary pa [illegible] under its influence. It is not, howe [illegible] nd on one occasion an improving [illegible] o two or three gramophone records became acutely agitated and relapsed into *a state of extreme depression*, while another patient recovering from an acute hallucinosis on first hearing some singing on the wireless, screamed "Oh, those awful voices again," and relapsed into a state of acute agitation. But these cases are exceptional.

The need that is felt for occupation and self-expression in some form by most individuals is illustrated if one walks through the wards of a mental hospital in which no form of occupation is provided. Patients are to be seen attempting to provide it for themselves, some may be seen knitting on hairpins, unravelled stockings being used for wool; odd things being made with ingenious tools they have created for themselves, sometimes beautiful embroidery is being done on old scraps of material. Some time ago an exhibition was held at a mental hospital in the United States of this kind of work done by patients in the hospital. Some of the exhibits had been created simply for the pleasure of producing something beautiful or useful; others, however, were of greater interest, for example, several complicated wood and metal machines one of which, the patient who made it claimed, controlled all the deliberations of the League of Nations, while another was said to regulate the movements of the universe and to direct the stars in their courses. The examination of this unguided occupation shows that what might be useful labour is being wasted, beautiful work often being done on worthless material; that great ingenuity is being used to no purpose, and in addition to this the work is often carrying the patient further into the world of phantasy and strengthening and emphasising delusions.

The occupation of the sick is still regarded by many as a diversion or amusement which will "take the man out of himself" for a short period and thus temporarily relieve his trouble, and this was no doubt the original purpose of those who attempted to employ their patients and it still serves this undoubtedly important purpose, but experience has shown those who have used it that it may be made to serve many other purposes and may, if prescribed and applied scientifically, prove a valuable form of therapy instead of an amusement which may or may not benefit the patient. It must be always remembered that occupational therapy is only a part of general therapy. It does not cure, nor does it claim to do so, but it does assist and hasten cure.

A CHILD GUIDANCE CONFERENCE

THE staffs of all the clinics in Great Britain organised on child guidance lines met in conference on Jan. 7th–8th in London, with Dr. William Moodie as president. After the first two sessions, the psychiatrists, psychologists, and social workers met separately under the chairmanship of Dr. Emanuel Miller, Dr. Lucie Fildes, and Miss Doris Robinson, respectively, who reported to a final meeting upon the general findings of the three sections.

The psychiatrists discussed the status of the social worker in relation to the psychiatrist and the families being investigated. While the social worker was trained to take a detached view of the field she was investigating, there was some danger, it was felt, of her establishing such emotional relationships with the family that the work of the psychiatrist might thereby be handicapped. While the value of the unity of psychiatrist, social worker, and psychologist was recognised, it was felt that a clinic was most successful where the physician maintained his authority in directing the social worker; in making suggestions as to approach; and deciding at case conferences where the future treatment of the child should lie—that is, in the psychiatric, the social, or the psychological field. The open case conference on a half-developed case was apt to misrepresent to casual visitors the work of child guidance. The investigation of play, both group and individual, was regarded as of first importance for diagnosis and cure in any clinic. Much could be gleaned of a child's social behaviour, intelligence, and emotional reactions from these observations, but it was premature to base their interpretation on current theories. The value of personality tests was considered, particularly the use of the Rohrschach tests; it was felt that discoveries could often be made on purely clinical lines without the use of time-devouring tests.

The social workers' group discussed means of organising their work under methods of treatment varying according to the views of the psychiatrist with whom they work. In small clinics where medical staff is part-time only, much responsibility for adjustment falls upon the social worker. Emphasis was laid on the need, when treating behaviour problems, of knowing working-class living conditions and standards, and of basing plans upon the real possibilities for adjustment.

In the psychological section discussion on clinical diagnosis and treatment developed the following points. Individual free play is recognised as a method of observation and as of probable therapeutic value: in certain selected cases more organised social and constructive play activity may be a profitable line of treatment. Control groups are necessary for the provision of data bearing on the value of treatment; though difficult, this method of evaluation is not impossible. The most hopeful line of growth of personality tests appears to be in the discovery of group factors underlying certain types of behaviour. While work in these directions has already given profitable results, much more experiment is needed before they can be used clinically.

The conference was held at the Institute of Medical Psychology under the auspices of the Child Guidance Council of Great Britain.

NURSING HOMES

Two small books recently issued provide between them probably as much information about nursing homes in this country as can be made available without infringing laws, written and unwritten. What a doctor really wants to know about a home is whether the accommodation and food is good for the price charged; whether the amount of actual nursing provided, and personal attention, day and night without extra charge for a "special," is at least up to the somewhat low standard customary in such institutions; whether there is a lift; whether the patient's bell is answered promptly; whether trained nurses only are employed; and many other things of this kind. This information is, however, unobtainable, except through personal experience; incidentally, a record of impressions of any particular home mentioned would soon make a directory of names and addresses a very useful document to its owner and his patients. Nursing Homes, 1933,[1] provides a list of registered nursing homes in England and Wales, Scotland, and Ireland, arranged according to counties and towns, with full address and telephone number, and a note whether medical, surgical, maternity, or only convalescent cases are accepted. Where, as sometimes occurs, more particulars are available among the advertisement pages, a reference to the appropriate page is also given; but even there the weekly terms are not always stated. London nursing homes are classified under postal districts. The book also contains a short list of mental homes, no indication being given whether certified or uncertified, or both types of cases are accepted. In the advertisement pages are set out trained nurses' institutes, hotels, and guest houses, a scholastic and nursery home section, and a physiotherapy section, as well as nursing and mental homes.

[1] Edited by J. Eaton Hosking. London: Ernest Benn, Ltd., 1933. Pp. 257. 4s.

The London Register of Nursing Homes and Medical Institutions, 1932–1933,[2] contains much useful information with regard to a limited area. Nursing coöperations and institutes are detailed, and lists of nursing homes are classified, perhaps redundantly, according to metropolitan boroughs, alphabetically, and also according to postal districts. The number of beds and terms per week are stated in most cases, as well as telephone numbers and type of cases admitted. The massage section contains "some members of the London branch (of the Chartered Society of Massage and Medical Gymnasts) in general practice." The up-to-date account of the accommodation available for paying patients in general and special London voluntary hospitals will be found useful, and also the lists of days and hours of attendance for out-patients in these hospitals. We could have spared the two pages devoted to "Therapeutic Suggestion," and would have welcomed, in both directories, a list of visiting nurses for private patients, or at least an asterisk indicating which nursing coöperations and institutes were prepared to supply these on demand.

HISTORY OF THE SAMARITAN FREE HOSPITAL

Dr. Oxford has been a member of the committee of the Samaritan Hospital for nearly half a century, and his vivid interest in its affairs has led to the collection of its annals.[3] These take the form of a brief annual chronicle from its foundation in 1847 in Gray-street, Manchester-square, as "The Gynepathic Institute Free Hospital," to 1930, and a very curious chronicle it makes. Many of the early years of the hospital's existence were marked by constant squabbles among the staff, medical and lay, and by wars of letters and pamphlets, ending in litigation and in the imprisonment of the chairman of the committee for unpaid costs. There were difficulties with secretaries, dispensers, and collectors; the first president, Lord Ashley, afterwards the philanthropic Earl of Shaftesbury, resigned; a subsequent one, Lord Cardigan, was summarily deposed on the grounds that he did not pay his subscription, failed to answer letters, and took no interest in the hospital. Here and there we get a touch of comic relief. The Rev. Robert Montgomery, the poet, who is now chiefly remembered as the subject of a scathing article by Macaulay, consented to preach on behalf of the institution on condition that the committee bought 100 copies (at 3*s.* 6*d.*) of his book on Luther, and offered to do it *again on the same terms*; collectors were paid a penny for every person who refused to give them a donation. A matron ordered grapes and asparagus for her own table and charged them in the bills as cabbages, and eventually committed the fatal mistake of being found on a racecourse by the president when she was supposed to be on duty. This, needless to say, was as long ago as 1883. Meanwhile the hospital had been gaining a high reputation for Spencer Wells's ovariotomy operations, his first successful one having been performed in 1858. The diet-table of patients recovering from this operation is a marvellous document. For the first few days they had beef-tea, arrowroot, and brandy "every five or ten minutes"; about the eighth day their diet was enriched by the addition of fish, light pudding, port or champagne. At the end of a fortnight they absorbed sustenances 11 times between 6 in the morning and 8 at night. After breakfast and before the 12 o'clock dinner they were thrice given wine and biscuits, and once bread and meat, with wine or beer. Brandy and soda accompanied dinner, and after tea there was a "pick-me-up," also of brandy and soda. At 8 o'clock in the evening the patient was comforted with "sandwiches and bitter beer," and hunger during the night was guarded against by a supply of "sandwiches, beef-tea, wine and brandy." The appendix, having been written in 1925, is, as the author admits, now out of date, and might with advantage have been either revised or omitted.

Vacancies

For further information refer to the advertisement columns

Banbury, Oxon, Horton General Hospital.—Res. M.O. At rate of £150.
Birmingham, Selly Oak Hospital.—Cas. O. At rate of £200.
Blackburn Royal Infirmary.—Res. H.P. and Fourth H.S. £175 and £150 respectively.
Bradford Royal Eye and Ear Hospital.—Jun. H.S. £150.
Bradford Royal Infirmary.—Three H.S.'s. Each at rate of £135.
Bristol Royal Infirmary.—H.P.'s and H.S.'s to Special Depts. Each at rate of £60.
Bristol, Southmead Hospital.—Res. Obstetric Officer. At rate of £200.

ADDRESSES AND ORIGINAL ARTICLES

ANÆSTHESIA FOR EUTOCIA*

By Frederick Roques, M.D., M.Chir. Camb.,
F.R.C.S. Eng., M.C.O.G.

SISTANT GYNÆCOLOGICAL AND OBSTETRIC SURGEON, MIDDLESEX
HOSPITAL; SURGEON TO OUT-PATIENTS, CHELSEA HOSPITAL
FOR WOMEN; GYNÆCOLOGICAL AND OBSTETRIC SURGEON,
ROYAL NORTHERN HOSPITAL

From time immemorial medical men have sought to leviate the pains of childbirth either by expediting e delivery of the child, and so curtailing the time uring which pain is felt, or by the administration of dative, hypnotic, anæsthetic, and analgesic drugs. e former method has been in general use since the cret of the Chamberlen family was discovered. The stetric forceps was kept a close secret by four ccessive generations of Chamberlens. More recently tempts have been made to shorten labour by means oxytocic drugs, such as pituitrin and its derivatives. e exhibition of such drugs to women in labour always dangerous and rarely successful, unless e head is on the perineum. I am not referring their use in small doses, and in conjunction with her drugs and with other means, for the induction labour. McIlroy advises against the use of tuitary extract, whatever the conditions are, before e end of the third stage of labour.

During our lifetime the efforts of the profession ave been chiefly directed towards the alleviation the pains by the sedative, anæsthetic, hypnotic, rcotic, and analgesic drugs. In reviewing a few of e methods, of which the number is legion, at our sposal to-day it is worth remembering that the eal one has not yet been discovered. The ideal is, ithout risk to the mother or her future child, to olish pain throughout labour. Since midwives e annually responsible for more than 60 per cent. the confinements in Great Britain it is evident at they will have to be allowed to use the ideal ethod, when it is found, if the pains of labour are be abolished in all women, or in a majority of omen. Fairbairn has pointed out that an Act of arliament would be required before midwives could permitted to administer the anæsthetic drugs, nless ordered to do so by a qualified medical practioner. The ideal method has not yet been disvered. When it is, and I hope not before, a Bill will doubt be presented to Parliament to legalise e administration of anæsthetic drugs by the midwife. ntil then she must, rightly or wrongly, confine erself to the use of such drugs as potassium bromide, loral hydrate, and opium, so far as the alleviation pain is concerned.

We must, therefore, relegate the ideal to the ture and discuss the practical methods at our isposal. Under the existing conditions of obstetric actice it is necessary that the method of alleviating ain shall, most importantly, neither alter the normal echanism of labour nor in any way increase the risk the mother or child; it must minimise pain roughout labour, so far as is possible under existing nditions: and it must not be unduly costly to e patient. The first of these desiderata is axiomatic. e second is demanded by the patient and the ird by both the poor patient and the grossly underid medical practitioner.

Although the ideal of a completely painless safe bour cannot be guaranteed to the patient, we can, by the skilful and judicious use of drugs, diminish her sufferings and, without danger to her or her future child, save her some of the agony endured by the mothers of former generations. Maybe the laity has had some effect in directing the attention of the profession in general, and of the obstetric specialty in particular, to the fear and loathing with which modern woman, not surprisingly, regards the pains of labour. Certainly the laity has, through the agency of funds collected by Mrs. Baldwin, Lady Balfour of Burleigh, and others, made it possible for the poor woman, if she chooses to be confined in a hospital which has accepted a grant from the committee, to be relieved of pain in a similar way to the rich. The popular agitation, like all popular movements, is not without reason; but, like all popular movements, it is unreasoned. Our patients are asking for something which it is not in our power to give.

Our duty is, surely, to avoid rashness and excess in either direction, neither promising a painless confinement on the one hand, nor condemning the patient to the tortures of the damned on the other. The former is unsafe and the latter unnecessary. The drug, or drugs, employed should be chosen to meet the requirements of the case, within the limits of safety. The routine use of one method, or one drug, shows a lack of knowledge and may cause the death of the mother or child. Besides, it spells mediocrity. It would be absurd to allow a highly neurotic woman to pass unrelieved through a prolonged first stage because this or that form of anæsthesia is to be used in the second. It would be ridiculous to produce amnesia during an almost painless, or short, first stage in a mentally well-balanced or plethoric individual. The method chosen must be the most suitable one for the patient.

The Sedative Drugs

The sedative drugs commonly employed in obstetric practice are four in number: potassium bromide, chloral hydrate, morphia, and hyoscine. They act on the brain, and the object in administering them is to secure rest, by abolishing the sensation of pain for a woman who is worn out by the undue prolongation of labour or by short, useless pains, and by soothing a hypersensitive, neurotic, or mentally unstable woman. Their exhibition is most frequently indicated during the first stage of labour in cases of disordered uterine action due to anomalies of the forces, and in cases in which labour is delayed from mechanical causes. The anomalies of the forces are sluggish uterus, exhausted uterus, spasmodic rigidity of the cervix and reflex nervous inhibition of the uterus; the mechanical causes are disproportion and malpresentation. Two or more of these abnormalities are frequently present at the same time in the cases which commonly cause great anxiety. The woman with a minor degree of pelvic contraction, whose child presents with the occiput posterior, whose membranes rupture early, whose uterus is sluggish and cervix slow to dilate, is well known as one of our most difficult problems, which is made more difficult by the relatives when the woman is being confined in her home. In such cases one of the sedative drugs, or a combination of the sedative drugs, is indicated.

POTASSIUM BROMIDE AND CHLORAL HYDRATE

Given in a mixture containing grs. 15 to 20 of each, potassium bromide and chloral hydrate have stood the test of time and they are safe. The mixture is made more effective by the addition of tincture of opium or by giving large doses of chloral hydrate, as practised by Eardley Holland. When given without morphia or opium, these drugs are frequently without effect, although they are occasionally useful as a placebo to the patient and her relatives.

---

* A lecture to post-graduates at the Middlesex Hospital.

MORPHIA

Morphia, or its parent, opium, is the most useful of the sedative drugs. Fairbairn has extolled its use. Its benefit is twofold. The central analgesic action is well known, while Bourne and Burn have shown that it has a local action, which is probably produced centrally, upon the uterine contractions, which are lessened in frequency, but increased in duration, after its hypodermic injection. A large number of short contractions is replaced by a smaller number of long ones; the former are of much less use than the latter in dilating the cervix. Moreover, this effect is produced without increasing the pain felt by the patient during each contraction; indeed, the pain caused by the long, slow contractions induced by morphia is, owing to the analgesic action of the drug, less than that caused by the previous short contractions.

The best results are obtained when it is given early. Fairbairn says that it should be given to the patient "when she is tiring, and before she is tired." It should always be given early in cases in which an unduly long labour is anticipated, on account of disproportion or malpresentation; when the patient is unduly nervous, hypersensitive, fearful or neurotic; and when the patient, often highly strung and nearly always fearful, is rapidly tired by short, ineffectual contractions. The first injection, of gr. $\frac{1}{6}$ to $\frac{1}{3}$, should be given as soon as the patient exhibits the signs of mental fatigue. It is often nnecessary to give a second dose.

hen the patient is unusually hypersensitive apprehensive it may be advisable to combine hia with hyoscine, although morphia alone is n efficacious. It should always be given to tients who are first seen after labour has been in rogress for many hours, before attempts at artificial delivery are made, unless the obstetric contraindication to its administration is present. In many cases, if not in most cases, spontaneous delivery occurs after the rest induced by an adequate injection of morphia.

The inestimable value of morphia in cases of eclampsia is well known. It is almost unnecessary to say that morphia, on account of its narcotic effect upon the respiratory centre of the child, should never be exhibited to a patient when her delivery is expected to occur within three hours, or a lesser period of time.

MORPHIA AND HYOSCINE

The literature on the combined use of morphia and hyoscine during labour is very extensive and exhaustive, if not exhausting. A continuous series of papers has appeared on the subject, from Steinbückel's paper, published in 1902, on "A method of inducing amnesia during labour by the hypodermic injection of scopolamine hydrobromate and morphine," until the publication of Claye's papers, in 1931 and 1932, in which he describes his method of using hyoscine hydrobromide. The most illuminating reviews on the subject are those of Lequeux, Siegel, and the committee of the obstetric section of the Royal Society of Medicine. The gravest disadvantage of this method is an undoubted suppression of the normal uterine function which results in a prolongation of labour and an increased incidence of forceps delivery; amnesia can be guaranteed only in three quarters of the cases. In spite of this it cannot be denied that the method possesses certain advantages; it is the treatment of election for reflex nervous inhibition of the uterus. But it is unsuitable for ordinary domiciliary midwifery; first, because it depends for its success upon the fulfilment of conditions which cannot be realised unless the patient is under the constant care of a specially trained personnel; secondly, because the relatives and friends of the patient become alarmed at her restlessness and excitement, which occur in many of the cases; and thirdly, because of the demand made upon the time of the obstetrician, who must be in almost continuous attendance throughout the labour, which usually lasts for 24 hours or more.

The Anæsthetic Drugs

There is universal agreement among practitioners that the acute pain which is experienced by the parturient woman towards the end of the second stage of labour should be relieved by one of the anæsthetic drugs, used as analgesics. Chloroform is, justly, the most popular; ether and a mixture of chloroform and ether are the alternatives.

Unfortunately the uterine contractions are diminished in strength and frequency by the inhalation of either of these anæsthetics. Dönhoff, Hensen, and Bourne and Burn have proved this beyond all doubt; clinical experience in the labour ward confirms their observations. Practically, however, the diminution in the strength of the contractions is not so great as seriously to delay delivery in the large majority of cases, provided the patient is only lightly anæsthetised.

Either chloroform or ether or a combination of chloroform and ether can, in small doses, be administered with safety towards the end of labour. Most obstetricians prefer chloroform to ether, although the reasons for this preference are seldom stated in text-books and papers on the subject. I think that chloroform is the more generally useful, for: (1) it is easier to induce analgesia with chloroform than with ether because the former acts more rapidly than the latter, particularly if the midwife is administering the anæsthetic under the direction of the practitioner; (2) analgesia can more rapidly and more surely be converted into anæsthesia at the appropriate time, by chloroform than by ether; (3) ether causes an excessive and troublesome secretion of mucus in the trachea and bronchi; and (4) vomiting, as Charles has observed, is usually more pronounced after ether than after chloroform.

The administration of chloroform, ether or a combination of the two should not be begun until the head can be felt through the perineum, and the chosen drug, or chosen mixture, should only be given to the woman during the pains until the head is imminently to be born, when surgical anæsthesia is required. Between the pains the mask should be removed from the woman's face, to be reapplied when she begins to feel the next pain. The time at which analgesia is induced is of the utmost importance. Chloroform and ether admittedly interfere with the normal mechanism of parturition. Their too early exhibition may result in delivery by the forceps, which could have been avoided, while undue procrastination in their exhibition may mar their effect. Experience dictates the best time to begin the administration of these drugs in an individual case; but, when there is a doubt, it is safer to wait. It is difficult, if not impossible, t continue analgesia, the patient quite naturally enting its cessation.

The danger of prolonged and deep chloroform æsthesia is well known. The production of algesia, by the discontinuous administration of the ug, requires from two to four drachms of chloroform. e quantity used should always be approximately imated and more than six drachms of chloroform ould not be given. When surgical anæsthesia is quired for the obstetric operations, including the plication of the forceps, either ether or a mixture chloroform and ether should be used.

CHLOROFORM

Chloroform may be administered on a mask by e midwife, acting on the instruction of the stetrician, or by an anæsthetist, acting in collabora-on with the obstetrician. Or it may be given by nker's inhaler worked by the patient herself. e have used Junker's inhaler for more than ten years the labour ward at Middlesex Hospital, and the tients have been satisfied. It is the safest of all æsthetics; for, so soon as the patient's volition eparts, she cannot obtain any more anæsthetic.

It may be given by the obstetrician or by the idwife, acting on the obstetrician's orders, in mpoules. This method has been tried, and is being ied, at Middlesex Hospital and at Queen Charlotte's Hospital. Rivett strongly advocates it, affirming that could be safely given by a midwife on her own itiative. Each ampoule contains 20 minims of hloroform. An ampoule is broken by the midwife n to a mask of lint and applied to the face of the atient when the head begins to show. A second mpoule is broken when the effect of the first begins o wear off, usually after one to three pains. About x to ten ampoules are used in an ordinary case. he midwife should be instructed not to give more han one ampoule during five minutes. This method ould probably be the safest and most convenient ethod for midwives to use if they were allowed to ive chloroform in cases in which they are not acting nder medical instructions.

Chloroform, of all the drugs used for the assuaging he pains of labour, is the most satisfactory under the revalent conditions of ordinary domiciliary mid-ifery, but again I insist that a limit must be set pon the quantity used, and the degree of anæsthesia ust be shallow.

USES OF ETHER

Ether or *a mixture of chloroform and ether* can be iven on a mask in the same way as chloroform, with inor differences—such as the thickness of the aterial of the mask—in technique. My preference s for chloroform, unless deep anæsthesia is required.

Ether and magnesium sulphate.—Another method f giving ether was introduced by Gwathmey in 1924. e has used it in more than 20,000 cases. It depends pon the induction of hypnosis, with subsequent mnesia, by the administration of drugs whose actions re complementary. The treatment is begun when he cervix is completely taken up and the uterine ontractions are good.

After an enema saponis at the beginning of treatment subcutaneous injection of gr. ¼ of morphine sulphate nd 2 c.cm. of a 50 per cent. solution of magnesium sulphate s given. After an interval of 20 minutes the magnesium ulphate is repeated without morphia. The morphia is iven for its sedative action, which is prolonged and increased y the concomitant and succeeding injections of magnesium ulphate.

When the sedative action begins to wear off, an alcoholic nd oily solution of ether and quinine is given by the rectum. he formula for this solution is: quinine alkaloid, grs. xx.; lcohol, ♏ xl.; ether, ℥ iiss.; olive oil, ad. ℥ iv. Immediately after the enema a third injection of 2 c.cm. of magnesium sulphate is given. Thereafter the patients sleep between the pains for a period of two to four hours, when complete consciousness begins to return. Another enema, containing grs. 10 of quinine, is then given. If necessary, a third enema containing grs. 10 of quinine is given. The depressant effect exerted by the morphia and ether on the uterine contractions is thought to be counteracted by the simultaneous exhibition of quinine.

Gwathmey, Davis and Harrar, and the other protagonists of this method claim success in 85 to 97 per cent. of the cases without danger to the mother or child. Labour, they say, is not prolonged, the forceps rate is not increased, and post-partum hæmorrhage is lessened. The method has been conspicuously unsuccessful in the few cases in which we have tried it at Middlesex Hospital. The method possesses the disadvantage of a somewhat complicated technique which necessarily entails frequent and repeated visits by the practitioner. For this reason it is unsuitable in private practice, while in hospitals it is difficult to secure the isolation and quietude which are essential to its success. It has been alleged that proctitis sometimes occurs, although this is denied by all authors with a wide experience.

NITROUS OXIDE AND OXYGEN

I have no hesitation in affirming that the best method of relieving the pains, without sacrificing eutocia, when repeated and prolonged attendance by the obstetrician is possible, when the services of more than one nurse are available if required, and when an anæsthetist, as well as an obstetrician, is in attendance, is by gas-and-oxygen. It is well known that this anæsthetic never affects the uterine contractions; it can be given for a long period without the risk of harming the mother or the child; it is a certain means of producing anæsthesia; the degree of anæsthesia can be rapidly altered, when necessary; and it does not have any unpleasant after-effects. We have given gas-and-oxygen, by Boyle's apparatus, with uniformly successful results in the labour ward of the Middlesex Hospital.

It is not usually necessary to begin the administration of gas-and-oxygen until the end of the first stage of labour, although it is not contra-indicated earlier. Lynch, who in 1915 was responsible for the introduction of this method of anæsthesia into obstetric practice, favours its commencement early in the first stage. A timely injection of morphia, or of morphia and scopolamine, during the first stage makes the use of gas-and-oxygen unnecessary before the cervix is fully dilated. The mask is applied to the patient's face at the onset of each contraction and removed between the contractions. During the delivery of the head the anæsthesia should be deepened by the addition of ether. The woman must never be allowed to become cyanosed. If she is, the baby will probably be born with blue asphyxia. A high degree of skill is necessary consistently to avoid cyanosis.

Although pre-eminently safe and sure, nitrous oxide and oxygen require for their proper administration the services of one highly skilled in their use; they are expensive, and the apparatus is heavy and cumbersome. The resulting cost of the method restricts its use to hospitals and patients of affluence.

The Hypnotic Drugs

During the past decade various derivatives of barbitonum have been introduced. The best known are avertin, sodium amytal, nembutal, and pernocton. Extravagant claims have been made for each of these drugs; but their number and the numerous methods is made more effective by the addition of tincture of opium or by giving large doses of chloral hydrate, as practised by Eardley Holland. When given without morphia or opium, these drugs are frequently without effect, although they are occasionally useful as a placebo to the patient and her relatives.

MORPHIA

Morphia, or its parent, opium, is the most useful of the sedative drugs. Fairbairn has extolled its use. Its benefit is twofold. The central analgesic action is well known, while Bourne and Burn have shown that it has a local action, which is probably produced centrally, upon the uterine contractions, which are lessened in frequency, but increased in duration, after its hypodermic injection. A large number of short contractions is replaced by a smaller number of long ones; the former are of much less use than the latter in dilating the cervix. Moreover, this effect is produced without increasing the pain felt by the patient during each contraction; indeed, the pain caused by the long, slow contractions induced by morphia is, owing to the analgesic action of the drug, less than that caused by the previous short contractions.

The best results are obtained when it is given early. Fairbairn says that it should be given to the patient "when she is tiring, and before she is tired." It should always be given early in cases in which an unduly long labour is anticipated, on account of disproportion or malpresentation; when the patient is unduly nervous, hypersensitive, fearful or neurotic; and when the patient, often highly strung and nearly always fearful, is rapidly tired by short, ineffectual contractions. The first injection, of gr. $\frac{1}{6}$ to $\frac{1}{3}$, should be given as soon as the patient exhibits the signs of mental fatigue. It is often unnecessary to give a second dose.

When the patient is unusually hypersensitive and apprehensive it may be advisable to combine morphia with hyoscine, although morphia alone is often efficacious. It should always be given to patients who are first seen after labour has been in progress for many hours, before attempts at artificial delivery are made, unless the obstetric contra-indication to its administration is present. In many cases, if not in most cases, spontaneous delivery occurs after the rest induced by an adequate injection of morphia.

The inestimable value of morphia in cases of eclampsia is well known. It is almost unnecessary to say that morphia, on account of its narcotic effect upon the respiratory centre of the child, should never be exhibited to a patient when her delivery is expected to occur within three hours, or a lesser period of time.

MORPHIA AND HYOSCINE

The literature on the combined use of morphia and hyoscine during labour is very extensive and exhaustive, if not exhausting. A continuous series of papers has appeared on the subject, from Steinbückel's paper, published in 1902, on "A method of inducing amnesia during labour by the hypodermic injection of scopolamine hydrobromate and morphine," until the publication of Claye's papers, in 1931 and 1932, in which he describes his method of using hyoscine hydrobromide. The most illuminating reviews on the subject are those of Lequeux, Siegel, and the committee of the obstetric section of the Royal Society of Medicine. The gravest disadvantage of this method is an undoubted suppression of the normal uterine function which results in a prolongation of labour and an increased incidence of forceps delivery; amnesia can be guaranteed only in three-quarters of the cases. In spite of this it cannot be denied that the method possesses certain advantages; it is the treatment of election for reflex nervous inhibition of the uterus. But it is unsuitable for ordinary domiciliary midwifery; first, because it depends for its success upon the fulfilment of conditions which cannot be realised unless the patient is under the constant care of a specially trained personnel; secondly, because the relatives and friends of the patient become alarmed at her restlessness and excitement, which occur in many of the cases; and thirdly, because of the demand made upon the time of the obstetrician, who must be in almost continuous attendance throughout the labour, which usually lasts for 24 hours or more.

The Anæsthetic Drugs

There is universal agreement among practitioners that the acute pain which is experienced by the parturient woman towards the end of the second stage of labour should be relieved by one of the anæsthetic drugs, used as analgesics. Chloroform is, justly, the most popular; ether and a mixture of chloroform and ether are the alternatives.

Unfortunately the uterine contractions are diminished in strength and frequency by the inhalation of either of these anæsthetics. Dönhoff, Hensen, and Bourne and Burn have proved this beyond all doubt; clinical experience in the labour ward confirms their observations. Practically, however, the diminution in the strength of the contractions is not so great as seriously to delay delivery in the large majority of cases, provided the patient is only lightly anæsthetised.

Either chloroform or ether or a combination of chloroform and ether can, in small doses, be administered with safety towards the end of labour. Most obstetricians prefer chloroform to ether, although the reasons for this preference are seldom stated in text-books and papers on the subject. I think that chloroform is the more generally useful, for: (1) it is easier to induce analgesia with chloroform than with ether because the former acts more rapidly than the latter, particularly if the midwife is administering the anæsthetic under the direction of the practitioner; (2) analgesia can more rapidly and more surely be converted into anæsthesia, at the appropriate time, by chloroform than by ether; (3) ether causes an excessive and troublesome secretion of mucus in the trachea and bronchi; and (4) vomiting, as Charles has observed, is usually more pronounced after ether than after chloroform.

The administration of chloroform, ether or a combination of the two should not be begun until the head can be felt through the perineum, and the chosen drug, or chosen mixture, should only be given to the woman during the pains until the head is imminently to be born, when surgical anæsthesia is required. Between the pains the mask should be removed from the woman's face, to be reapplied when she begins to feel the next pain. The time at which analgesia is induced is of the utmost importance. Chloroform and ether admittedly interfere with the normal mechanism of parturition. Their too early exhibition may result in delivery by the forceps, which could have been avoided, while undue procrastination in their exhibition may mar their effect. Experience dictates the best time to begin the administration of these drugs in an individual case; but, when there is a doubt, it is safer to wait. It is difficult, if not impossible, to ontinue analgesia, the patient quite naturally enting its cessation.

The danger of prolonged and deep chloroform esthesia is well known. The production of algesia, by the discontinuous administration of the ug, requires from two to four drachms of chloroform. e quantity used should always be approximately imated and more than six drachms of chloroform ould not be given. When surgical anæsthesia is quired for the obstetric operations, including the plication of the forceps, either ether or a mixture chloroform and ether should be used.

CHLOROFORM

Chloroform may be administered on a mask by e midwife, acting on the instruction of the stetrician, or by an anæsthetist, acting in collaboraon with the obstetrician. Or it may be given by nker's inhaler worked by the patient herself. e have used Junker's inhaler for more than ten years the labour ward at Middlesex Hospital, and the tients have been satisfied. It is the safest of all æsthetics; for, so soon as the patient's volition parts, she cannot obtain any more anæsthetic.

It may be given by the obstetrician or by the idwife, acting on the obstetrician's orders, in npoules. This method has been tried, and is being ied. at Middlesex Hospital and at Queen Charlotte's ospital. Rivett strongly advocates it, affirming that could be safely given by a midwife on her own itiative. Each ampoule contains 20 minims of loroform. An ampoule is broken by the midwife n to a mask of lint and applied to the face of the atient when the head begins to show. A second npoule is broken when the effect of the first begins wear off, usually after one to three pains. About x to ten ampoules are used in an ordinary case. he midwife should be instructed not to give more an one ampoule during five minutes. This method ould probably be the safest and most convenient ethod for midwives to use if they were allowed to ive chloroform in cases in which they are not acting nder medical instructions.

Chloroform, of all the drugs used for the assuaging e pains of labour, is the most satisfactory under the revalent conditions of ordinary domiciliary midifery, but again I insist that a limit must be set pon the quantity used, and the degree of anæsthesia ust be shallow.

USES OF ETHER

Ether or *a mixture of chloroform and ether* can be iven on a mask in the same way as chloroform, with inor differences—such as the thickness of the aterial of the mask—in technique. My preference for chloroform, unless deep anæsthesia is required.

Ether and magnesium sulphate.—Another method f giving ether was introduced by Gwathmey in 1924. le has used it in more than 20,000 cases. It depends pon the induction of hypnosis, with subsequent mnesia, by the administration of drugs whose actions re complementary. The treatment is begun when he cervix is completely taken up and the uterine ontractions are good.

After an enema saponis at the beginning of treatment subcutaneous injection of gr. ¼ of morphine sulphate nd 2 c.cm. of a 50 per cent. solution of magnesium sulphate given. After an interval of 20 minutes the magnesium alphate is repeated without morphia. The morphia is iven for its sedative action, which is prolonged and increased y the concomitant and succeeding injections of magnesium alphate.

When the sedative action begins to wear off, an alcoholic d oily solution of ether and quinine is given by the rectum. formula for this solution is: quinine alkaloid, grs. xx.; cohol, ♏ xl.; ether, ℥ iss.; olive oil, ad. ℥ iv. Immediately after the enema a third injection of 2 c.cm. of magnesium sulphate is given. Thereafter the patients sleep between the pains for a period of two to four hours, when complete consciousness begins to return. Another enema, containing grs. 10 of quinine, is then given. If necessary, a third enema containing grs. 10 of quinine is given. The depressant effect exerted by the morphia and ether on the uterine contractions is thought to be counteracted by the simultaneous exhibition of quinine.

Gwathmey, Davis and Harrar, and the other protagonists of this method claim success in 85 to 97 per cent. of the cases without danger to the mother or child. Labour, they say, is not prolonged, the forceps rate is not increased, and post-partum hæmorrhage is lessened. The method has been conspicuously unsuccessful in the few cases in which we have tried it at Middlesex Hospital. The method possesses the disadvantage of a somewhat complicated technique which necessarily entails frequent and repeated visits by the practitioner. For this reason it is unsuitable in private practice, while in hospitals it is difficult to secure the isolation and quietude which are essential to its success. It has been alleged that proctitis sometimes occurs, although this is denied by all authors with a wide experience.

NITROUS OXIDE AND OXYGEN

I have no hesitation in affirming that the best method of relieving the pains, without sacrificing eutocia, when repeated and prolonged attendance by the obstetrician is possible, when the services of more than one nurse are available if required, and when an anæsthetist, as well as an obstetrician, is in attendance, is by gas-and-oxygen. It is well known that this anæsthetic never affects the uterine contractions; it can be given for a long period without the risk of harming the mother or the child; it is a certain means of producing anæsthesia; the degree of anæsthesia can be rapidly altered, when necessary; and it does not have any unpleasant after-effects. We have given gas-and-oxygen, by Boyle's apparatus, with uniformly successful results in the labour ward of the Middlesex Hospital.

It is not usually necessary to begin the administration of gas-and-oxygen until the end of the first stage of labour, although it is not contra-indicated earlier. Lynch, who in 1915 was responsible for the introduction of this method of anæsthesia into obstetric practice, favours its commencement early in the first stage. A timely injection of morphia, or of morphia and scopolamine, during the first stage makes the use of gas-and-oxygen unnecessary before the cervix is fully dilated. The mask is applied to the patient's face at the onset of each contraction and removed between the contractions. During the delivery of the head the anæsthesia should be deepened by the addition of ether. The woman must never be allowed to become cyanosed. If she is, the baby will probably be born with blue asphyxia. A high degree of skill is necessary consistently to avoid cyanosis.

Although pre-eminently safe and sure, nitrous oxide and oxygen require for their proper administration the services of one highly skilled in their use; they are expensive, and the apparatus is heavy and cumbersome. The resulting cost of the method restricts its use to hospitals and patients of affluence.

The Hypnotic Drugs

During the past decade various derivatives of barbitonum have been introduced. The best known are avertin, sodium amytal, nembutal, and pernocton. Extravagant claims have been made for each of these drugs; but their number and the numerous methods recommended by different authors for their administration strongly suggests to me that none of them is absolutely reliable if given in safe doses. Nembutal, given orally with chloral hydrate as recommended by O'Sullivan and Craner, is probably the most satisfactory; sodium amytal appears to be the least desirable. They are all given for their hypnotic effect, in the hope that when consciousness is regained, after the artificially induced sleep, the woman will be amnesic regarding the pains of labour after the induction of hypnosis. The published reports clearly indicate that each of the four drugs is successful in a majority of the cases in which it has been used, but they all possess certain inherent disadvantages. First, the patient may become very excited, even maniacal, while under the influence of any of them. This demands a greater number of attendants than are ordinarily present at a confinement. The excitement appears to be greater with sodium amytal than with any of the other three drugs; but, I must admit, I have never used sodium amytal. My experience of avertin, pernocton, and nembutal is that excitement does sometimes occur; the patients must, therefore, be carefully watched. Secondly, it is impossible accurately to gauge the dose. It may be known that x mg. or y c.cm. per kg. of body-weight is a safe and effective dose in a majority of cases, but idiosyncrasy is not uncommon. On the one hand, the recommended dose may be without effect, while, on the other hand, it may cause collapse. Thirdly, and in spite of assertions to the contrary, my experience leads me to believe that the barbiturates interfere with the natural course of labour, which is prolonged by their use and has, more frequently than usual, to be terminated by the forceps. Fourthly, the correct treatment of overdosage is not known. Fifthly, and less importantly, one of the anæsthetic drugs is almost always required to supplement the hypnotic drug during delivery.

These disadvantages limit the use of the barbiturates. They should only be used in hospitals, well-conducted nursing-homes, and in private houses in which an adequate number of assistants can be employed. In these circumstances it seems unwise to replace morphia, judiciously exhibited during the first stage of labour, and gas-and-oxygen skilfully administered during the second stage, by hypnotic drugs of uncertain and possibly dangerous action.

NEMBUTAL

Nembutal, sodium-ethyl-methyl-butyl barbiturate, is one of the latest of the barbiturates to be introduced into obstetric practice. This drug undergoes decomposition by hydrolysis if kept in contact with the air. The manufactured product is, therefore, sold in capsules covered with a coat of gelatin; each ampoule contains grs. 1½ of nembutal. O'Sullivan and Craner have described, in a well-balanced and unbiased paper, their method of giving nembutal with chloral hydrate. The chloral hydrate is given in three ounces of freshly prepared lemonade with sugar ten minutes after the capsules containing the nembutal have been swallowed. If the chloral hydrate is given immediately after the nembutal, or if the quantity of fluid in which the chloral hydrate is dissolved is too bulky, the patient vomits. Both drugs are given by the mouth. The first dose, consisting of grs. 3 of nembutal (two capsules) and grs. 30 of chloral hydrate, is given to primiparæ when the cervix is two-fifths to three-fifths dilated and to multiparæ when it is one-fifth to two-fifths dilated, regular uterine contractions being present.

The time of administration of the drugs is impor because the uterine contractions are diminished strength and frequency if they are given too s and they do not have time to act if given too l Failures occurred in cases in which they were gi less than an hour and a half before delivery. T second dose, consisting of the same quantity of t drug, should be given about two hours after the fir subsequent doses should be given at intervals three hours: the total dosage should not exc grs. 7½ of nembutal and grs. 120 of chloral hydra O'Sullivan and Craner are satisfied that their meth is safe and reliable. Indeed, they are of the that nembutal and chloral hydrate could be gi by midwives without danger, if the midwives follow their technique without any variation. Their resu are, undoubtedly, encouraging: labour was painl in 62 per cent. of their cases, varying degrees amnesia were achieved in their other cases, but i 7 per cent. the method failed.

PERNOCTON

Pernocton is the latest derivative of barbitur acid to be introduced into obstetric practice. It composed of a 10 per cent. solution of the sodium sa of secondary butyl-β-bromalbyl barbituric aci Bumm brought pernocton into prominence in and 1927, when he published the results of the ana thetic use of the drug for gynæcological operatio and of his experiments with it on dogs. Bumm research was due to his dissatisfaction with pernocton's barbituric predecessor. He found eviden of renal and hepatic damage in three cases aft using somnifen; he says that that drug produc undue excitement and that the post-operative sle is unduly prolonged. On the other hand he foun that pernocton does not possess these three di advantages. He found that the minimum lethal do of pernocton was ten times greater than the minim effective dose: when it was given to dogs in leth doses death was due to paralysis of the respirato centre. Pernocton produces amnesia by its acti on the brain. It is not split into toxic substanc after its introduction into the body; after i reduction to acetonyl barbituric acid, it underg further reduction into inert substances which are n toxic.

It can be given either intravenously or int muscularly. It must not be given subcutaneousl because the skin sloughs over the site of the injecti

The injection should be made very slowly when t intravenous route is chosen, in order that the concentrati of pernocton in the blood shall not be raised too quickl the overlying skin will slough if any of the solution is inject outside the vein. The injection of an ampoule contain 2·2 c.cm. should not occupy less than two and a half minut It should, therefore, take five minutes to inject the conte of two ampoules. Matters states that the intraven route is the better because it permits the correct rate absorption by the nerve-cells and ensures accurate dosa other authorities agree.

The solution is sold in ampoules containing 2·2 c.c of the 10 per cent. solution. Goldschmidt gives 1 c.c of pernocton for each 12·5 kg. (27·5 lb.) of body-weig Goetz, 1 c.cm. for each 10 kg. (22·2 lb.) of body-weig Matters, 1 c.cm. for each 12 kg. (26·4 lb.) to 15 kg. (33·1 l of body-weight.

A woman weighing 112 lb. (8 st.) would, therefore given 4·3 c.cm. of the solution by Goldschmidt, slig more than 5 c.cm. by Goetz, and from 3·4 to 4·2 c.cm. Matters.

The other authors whose papers I have read are not precise in estimating the correct dose. Hole recomm a dose of 4·4 to 7·5 c.cm., the dose depending on the wei of the patient. Brown, Moloy, and Laird prescribe a d of 4·4 c.cm. as the initial dose for patients of average wei If a second dose is required, they usually give 2·2 c.c but they have frequently given 4·4 c.cm.

hese figures and opinions indicate that, if pernocton sed, the first intravenous injection should consist about 4·4 c.cm., that is a little less or a little more n the contents of two ampoules, when the woman ghs 112 lb. (8 st.).

ach author claims reasonable success with per- ton in the dose he recommends. This dose is, refore, an effective dose, an observation which have been able to confirm at the Middlesex spital in the few cases in which we have used nocton. Bumm found, when experimenting on that the minimal lethal dose was ten times great as the minimal effective dose. It would, refore, appear that 44 c.cm. (more than nine poules) of pernocton would be required to kill a man weighing 8 st. If this is indeed a fact, a t dose of 4·4 c.cm. can safely be given.

he first injection should be made when the pains of our are definitely established, most usefully when the nan is becoming distressed and the degree of cervical tation is small. Brown, Moloy, and Laird give it n the uterine contractions are powerful and recur at rvals of three to five minutes. The patients fall into p sleep during the injection of the drug. They remain ep for 30 minutes to 5 hours, although they may, icularly when the effect of the drug is beginning to wane, in or return to apparent consciousness during the con- tions of the uterus; they do not afterwards remember n happenings.

second injection is indicated when the patient com- ely regains consciousness and delivery is not expected four hours. The second dose should not be greater n half the first; it should be given more slowly than the

roecke and Vogt in Germany, and Bohler in France e been using pernocton for treating eclampsia. gt also advocates its use during labour in pre- mptic patients. They all claim greater success n can be achieved by any other method of treat- nt, including that of Stroganoff. There is general eement among Continental authors who have used nocton in large numbers of cases that it does not m the mother, provided the dosage and the nique of injection are correct. Both the first the second stages of labour are said to be shortened her than lengthened by its use, although the lence of this appears to be based upon general ression, not upon accurate analyses of large series ases.

ts greatest disadvantage is the necessity for tinuous observation of the patient, who should er be left after its exhibition. The restlessness and itement of some of the patients may be difficult to trol. Restlessness of greater or lesser degree rred in 26 per cent. of 100 cases recorded by midt; several of his patients developed incon- nce of urine and fæces while under the influence the drug. These facts prohibit its use outside pitals and nursing-homes, except for wealthy ients. The relatively short and variable duration he anæsthesia is a minor disadvantage. Bourne Williams point out that an antidote, for a case verdosage, is not known. It is generally accepted pernocton does not have an untoward effect he child, although three of the children in Bohler's es of 192 cases were affected.

AVERTIN

uring the year 1926 avertin, or tribrom-ethyl- hol, which had proved satisfactory as a basal sthetic for surgical purposes, began to be used he Continent for the production of hypnosis and lting amnesia during labour. Martin, Benthin, other Continental authors praised it unstintingly; 930 Connell published, in an important paper, first results recorded in the United Kingdom.

The technique of its administration is easy; the details are found in his paper in which he recommends the safe dose of 0·075 c.cm. of avertin fluid per kg. of body-weight, that is, about 4·5 c.cm. for a woman weighing 126 lb. (9 st.). The relative simplicity of the technique and apparatus required for its rectal administration are undeniable advantages. Connell recommends the instillation of avertin when the cervix is two-thirds dilated in primiparæ and half dilated in multiparæ, provided the uterine contractions are strong and antenatal examination has pointed to normal labour. Stander has shown that the administration of 1000 mg. of avertin per kg. of body-weight does not produce any alteration in the amount of non-protein nitrogen, urea nitrogen, uric acid, lactic acid, creatinine, inorganic chlorides and carbon dioxide in the blood; the amount of sugar is slightly increased.

Its greatest disadvantage is the excitement which sometimes follows its exhibition. Both Rumpf, who prefers avertin to pernocton, and Kienlin, who prefers pernocton to avertin, refer to the excited state of many of the patients. I have confirmed this at the Royal Northern Hospital in some of the cases in which I have used avertin. These observations clearly indicate that a patient should not be left after the rectal instillation of the drug and that more than one assistant must be present in order, if necessary, to restrain her. Labour is undoubtedly prolonged and, therefore, the incidence of delivery by the forceps is increased.

Naujok discusses several cases of maternal death following, or during, avertin amnesia. He says that veronal, pantopon, and ethyl chloride should never be given after, with or before avertin. He refers to two cases of transitory exanthema, presumably due to avertin, during the puerperium. He is enthusiastic about the value of avertin in the treatment of eclampsia. Stander is against its use in eclampsia because it is detoxicated in the liver; the function of that organ is thought already to be over-taxed by eclampsia. The children do not appear to be directly harmed by avertin, but prolongation of labour and instrumental delivery cannot be of benefit either to the mother or the child. Each dose of avertin must be freshly prepared because of its rapid decomposition into the irritating and nocuous dibrom-acetaldehyde.

SODIUM AMYTAL

Sodium amytal (iso-amyl-ethyl barbituric acid) has enjoyed some measure of popularity in the United States during the past few years. It can be given orally, intravenously, intramuscularly, or rectally.

Most authors recommend the intravenous route and give from grs. 7 to 10. Ruth and Paxon recommend giving the injection when the contractions of the uterus occur every two to four minutes and last from 45 seconds to one minute, and when the cervix is taken up and about 5 cm. dilated. Featherstone and Tait give the large intravenous dose of grs. 15 shortly before the cervix becomes fully dilated. Drabkin and Hurst report satisfactory results by the rectal route, giving 30 mg. per kg. of body-weight. The uterine contractions were weakened in some of their patients and abolished in two.

Hamblen and Hamblin favour the oral route. They give an initial dose of grs. 6 to 15 as soon as labour is definitely established and the cervix begin to dilate—earlier than most other authors. One or two additional doses are given when necessary, but the total dosage should not exceed grs. 30. They claim that the drug is as efficacious when given by the mouth as when given intravenously; this claim is based upon their belief that the depth of the narcosis depends upon the dose and not upon the method of administration.

The great drawback to the use of sodium amytal is the excitement which so often ensues and is referred recommended by different authors for their administration strongly suggests to me that none of them is absolutely reliable if given in safe doses. Nembutal, given orally with chloral hydrate as recommended by O'Sullivan and Craner, is probably the most satisfactory; sodium amytal appears to be the least desirable. They are all given for their hypnotic effect, in the hope that when consciousness is regained, after the artificially induced sleep, the woman will be amnesic regarding the pains of labour after the induction of hypnosis. The published reports clearly indicate that each of the four drugs is successful in a majority of the cases in which it has been used, but they all possess certain inherent disadvantages. First, the patient may become very excited, even maniacal, while under the influence of any of them. This demands a greater number of attendants than are ordinarily present at a confinement. The excitement appears to be greater with sodium amytal than with any of the other three drugs; but, I must admit, I have never used sodium amytal. My experience of avertin, pernocton, and nembutal is that excitement does sometimes occur; the patients must, therefore, be carefully watched. Secondly, it is impossible accurately to gauge the dose. It may be known that *x* mg. or *y* c.cm. per kg. of body-weight is a safe and effective dose in a majority of cases, but idiosyncrasy is not uncommon. On the one hand, the recommended dose may be without effect, while, on the other hand, it may cause collapse. Thirdly, and in spite of assertions to the contrary, my experience leads me to believe that the barbiturates interfere with the natural course of labour, which is prolonged by their use and has, more frequently than usual, to be terminated by the forceps. Fourthly, the correct treatment of overdosage is not known. Fifthly, and less importantly, one of the anæsthetic drugs is almost always required to supplement the hypnotic drug during delivery.

These disadvantages limit the use of the barbiturates. They should only be used in hospitals, well-conducted nursing-homes, and in private houses in which an adequate number of assistants can be employed. In these circumstances it seems unwise to replace morphia, judiciously exhibited during the first stage of labour, and gas-and-oxygen skilfully administered during the second stage, by hypnotic drugs of uncertain and possibly dangerous action.

NEMBUTAL

Nembutal, sodium-ethyl-methyl-butyl barbiturate, is one of the latest of the barbiturates to be introduced into obstetric practice. This drug undergoes decomposition by hydrolysis if kept in contact with the air. The manufactured product is, therefore, sold in capsules covered with a coat of gelatin; each ampoule contains grs. 1½ of nembutal. O'Sullivan and Craner have described, in a well-balanced and unbiased paper, their method of giving nembutal with chloral hydrate. The chloral hydrate is given in three ounces of freshly prepared lemonade with sugar ten minutes after the capsules containing the nembutal have been swallowed. If the chloral hydrate is given immediately after the nembutal, or if the quantity of fluid in which the chloral hydrate is dissolved is too bulky, the patient vomits. Both drugs are given by the mouth. The first dose, consisting of grs. 3 of nembutal (two capsules) and grs. 30 of chloral hydrate, is given to primiparæ when the cervix is two-fifths to three-fifths dilated and to multiparæ when it is one-fifth to two-fifths dilated, regular uterine contractions being present.

The time of administration of the drugs is impor because the uterine contractions are diminished strength and frequency if they are given too s and they do not have time to act if given too l Failures occurred in cases in which they were gi less than an hour and a half before delivery. T second dose, consisting of the same quantity of t drug, should be given about two hours after the fir subsequent doses should be given at intervals three hours: the total dosage should not exce grs. 7½ of nembutal and grs. 120 of chloral hydra O'Sullivan and Craner are satisfied that their meth is safe and reliable. Indeed, they are of the opin that nembutal and chloral hydrate could be giv by midwives without danger, if the midwives follow their technique without any variation. Their resu are, undoubtedly, encouraging: labour was pain in 62 per cent. of their cases, varying degrees o amnesia were achieved in their other cases, but i 7 per cent. the method failed.

PERNOCTON

Pernocton is the latest derivative of barbitur acid to be introduced into obstetric practice. It i composed of a 10 per cent. solution of the sodium sa of secondary butyl-β-bromalbyl barbituric acid Bumm brought pernocton into prominence in 19 and 1927, when he published the results of the an thetic use of the drug for gynæcological operatio and of his experiments with it on dogs. Bumm research was due to his dissatisfaction with somnife pernocton's barbituric predecessor. He found eviden of renal and hepatic damage in three cases aft using somnifen; he says that that drug produce undue excitement and that the post-operative sle is unduly prolonged. On the other hand he foun that pernocton does not possess these three di advantages. He found that the minimum lethal do of pernocton was ten times greater than the minim effective dose: when it was given to dogs in leth doses death was due to paralysis of the respirator centre. Pernocton produces amnesia by its actio on the brain. It is not split into toxic substance after its introduction into the body; after r reduction to acetonyl barbituric acid, it underg further reduction into inert substances which are n toxic.

It can be given either intravenously or intra muscularly. It must not be given subcutaneou because the skin sloughs over the site of the injecti

The injection should be made very slowly when th intravenous route is chosen, in order that the concentrat of pernocton in the blood shall not be raised too quickly the overlying skin will slough if any of the solution is inject outside the vein. The injection of an ampoule contain 2·2 c.cm. should not occupy less than two and a half minu It should, therefore, take five minutes to inject the cont of two ampoules. Matters states that the intraven route is the better because it permits the correct rate absorption by the nerve-cells and ensures accurate dosag other authorities agree.

The solution is sold in ampoules containing 2·2 c.c of the 10 per cent. solution. Goldschmidt gives 1 c.c of pernocton for each 12·5 kg. (27·5 lb.) of body-weig Goetz, 1 c.cm. for each 10 kg. (22·2 lb.) of body-weig Matters, 1 c.cm. for each 12 kg. (26·4 lb.) to 15 kg. (33 l of body-weight.

A woman weighing 112 lb. (8 st.) would, therefore, given 4·3 c.cm. of the solution by Goldschmidt, sligh more than 5 c.cm. by Goetz, and from 3·4 to 4·2 c.cm. Matters.

The other authors whose papers I have read are no precise in estimating the correct dose. Hole recomm a dose of 4·1 to 7·5 c.cm., the dose depending on the we of the patient. Brown, Moloy, and Laird prescribe a d of 4·1 c.cm. as the initial dose for patients of average we If a second dose is required, they usually give 2·2 c.c but they have frequently given 1·1 c.cm.

ompletely failed. The urine at the onset of an attack howed considerable amounts of acetone and urobilin. he patient was ordered to take glucose ½ oz. twice aily and Decholin tablets—one, three times daily, ith instructions to double the dose if he felt an ttack developing. Seven months later he had not ad another attack, although for the previous six ears he had not been free for longer than four eeks.

The differential diagnosis between cholecystitis nd abdominal migraine is difficult clinically—an nset in youth, more rapid recovery after the attacks, nd less definite and localised abdominal tenderness ould be in favour of a diagnosis of abdominal igraine.

There are undoubtedly instances of migraine elieved or cured by cholecystectomy, but most cases f this "biliary" type are, in our opinion, associated ith hepatic rather than gall-bladder dysfunction, nd will respond to the administration of glucose, bile acids, and a general dietetic restriction.

Stimulation of the flow of bile by duodenal atheterisation with or without the introduction of [illegible] sulphate has been successful in several [illegible] ok[3] has recommended the following régime: after a complete starvation day, give 2 to 4 drachms of a 50 per cent. solution of magnesium sulphate one hour before rising; during this hour the patient lies semiprone on the right side, and he then takes half a pint of hot water or hot tea. This procedure is repeated each week; in addition, fats and in certain cases eggs, chocolate, cocoa, coffee, and alcohol are eliminated from the diet.

Some of these cases resemble clinically the type described by Newman as due to dyskinesia of the gall-bladder, and in these treatment by atropine or belladonna is indicated. In others of the "alimentary" group it appears that duodenal stasis is the primary lesion. X rays may show a wide dilatation with delay, or more usually a "to and fro" movement in the duodenum. Higgins[4] has drawn attention to the occurrence in chronic duodenal ileus of migraine which is relieved by duodeno-jejunostomy.

Opinions differ as to the part played by the "liver-gall-bladder-gastro-duodenal" factor in migraine, but it would appear certain that, although its importance has been exaggerated by some writers, yet there are many cases which are intimately associated with hepatic dysfunction and relieved by its correction.

DIETETIC TYPE

In close association with the above group is the dietetic type; but it is improbable that diet plays an important part in the production of migraine. All manner and varieties of diets have been recommended from time to time—a high fat or a low fat diet, withdrawal of all forms of animal protein from the food, a full carbohydrate diet or one with carbohydrates eliminated—each advocate of a particular diet extolling its virtues and turning a deaf ear to the claims of its rivals. If in a particular case it seems probable from a careful history that diet is an important predisposing factor, then it is justifiable to try the value of sensitisation tests as for asthma. If a positive result is obtained it is clear that the offending article must be excluded; if negative, then omit, first, carbohydrates; secondly, animal protein; and, if still unsuccessful, prescribe a purine-free diet.

Many diets have been recommended on a purely empirical basis, but in such a protean disease it seems unwise to do this. It is probable that quantity and regularity are more important factors than quality.

A METABOLIC TYPE

The observations that acetone is present in the breath before an attack, and that there is an alteration in the pH and alkali reserve in an attack, although between the attacks the figures are normal, have led to treatment by withdrawal of fats and giving glucose and alkalis. Eight injections of 2·0 g. of an 80 per cent. solution of sodium carbonate are given intravenously in addition to sodium bicarbonate by mouth. On the other hand, Barborka[5] reports the results of the treatment of 50 cases of typical migraine by a ketogenic diet—80 per cent. of these patients being benefited by the diet.

The allegation that migraine is due to an inherited or acquired defect in protein metabolism—an inability to detoxicate putrefactive substances derived from animal protein in the intestinal canal—has led to treatment by withdrawal of proteins from the diet, changing the intestinal flora by the addition of *Bacillus acidophilus*, and the relief of spastic constipation in order to secure copious daily evacuations (Diamond[6]). Abnormalities in the uric acid metabolism are invoked to explain other cases of migraine.

The frequent onset of migraine in the early morning, the occurrence of attacks in many cases after prolonged physical exertion or after starvation, the observations of low blood-sugar readings in several cases, and the relief, especially in children, by the administration of glucose have suggested that transitory hypoglycæmia may be an important factor in the production of migraine. We feel that in many cases definite relief is given by the administration of glucose either between the attacks or as soon as notice of an attack is given; although, on the other hand, there are cases recorded where the ingestion of sugar has apparently precipitated an attack. It is difficult to correlate these views and findings.

Muck[7] has produced hemicranial attacks in patients subject to migraine by the induction of alkalosis by hyperpnœa.

It is extremely difficult to assess the importance of the metabolic factor in migraine, but in obscure and therapeutically refractory cases, where investigation reveals a metabolic error, the appropriate treatment should be instituted.

The association of headache, sickness, polyuria, throbbing heart, and constricted peripheral blood-vessels has suggested the resemblance to the clinical picture of a "contracted kidney," and the view has been promulgated that in migraine there is an accumulation in the blood of some toxic substance requiring elimination. The occurrence of migraine in undoubted cases of chronic nephritis has led to the description of the *nephritic* type. We must bear in mind this association, though it is difficult to be certain of the nature or importance of the relationship between these two conditions.

AN ALLERGIC TYPE

Some regard the fundamental cause of migraine as an anaphylactic shock. The well-known relationship with asthma, urticaria, and angioneurotic œdema supports this view. Pagniez[8] has given a full account of the appropriate measures directed to the desensitisation of the nervous system, and good results have been claimed from the administration of weekly injections of 1 c.cm. of horse serum for two months, or from taking 0·5 g. of peptone before each meal or injecting peptone subcutaneously. In one of our cases it was found that the migraine attack occurred only after eating chocolate, and was cured by the elimination of chocolate from the diet; in to by all authors. Idiosyncrasies are common. Hamblen and Hamblin describe a case in which the patient remained fully conscious after grs. 30, and another case in which serious collapse occurred after grs. 21.

CONCLUSION

The logical conclusion to be drawn from a review of the incredibly large number of drugs and methods at present in vogue for the production of analgesia, with subsequent amnesia, during labour is that the most suitable method for the ordinary case, with one doctor and one midwife in attendance, having regard to safety, ease of administration and expense, is morphia in the first stage and chloroform towards the end of the second stage. For patients in hospitals and nursing-homes, and for affluent patients in their own homes, the most satisfactory drug in the first stage is morphia and, throughout the whole of the second stage, gas-and-oxygen, which should be supplemented by ether towards the end of the second stage.

BANBRIDGE GENERAL HOSPITAL.—The Duchess of Abercorn last week formally opened the new district hospital at Banbridge, County Down, which has cost £56,000. The former union house has been reconstructed and remodelled, and unsuitable parts of the building and enclosing walls have been removed to obtain additional air and sun. One of the wings is fitted as a maternity home, and another as the nurses' home. The total number of beds contemplated is 93, but in an emergency a greater number can be accommodated. Some distance at the rear is a fever hospital, with accommodation for 44 patients. The building stands high in grounds full of old trees, and the windows command glimpses of the Mourne mountains.

MIGRAINE *

(Concluded from p. 126)

Ætiological and Therapeutic Considerations

WE have been forced to the conclusion that migrai constitutes an extremely complex problem, th there are many types and variants, and that th are many different factors—external and constitutional—at work in the production of this ve distressing malady. In discussing the symptomatology reference has already been made to five clini types—bilious, ocular, menstrual, cerebral, an allergic—to migraine-epilepsy, to the migrain constitution, and to several other factors which w consider play rôles of varying importance. We propo now to extend the number of these groups and discu them in somewhat greater detail. The treatment wi naturally vary with the suspected causation, and w think it will be most convenient if, at the end of eac paragraph on a particular type, we give a bri outline of the treatment which has been advocat as most likely to benefit that type.

AN ALIMENTARY TYPE

Particular attention has been paid by Fre authors to the "bilious," "abdominal" or "du denal" type of migraine, in which it is thoug that the causative factor is an abnormality in t gastro-intestinal tract or liver. Hunt[1] has discu carefully the differential diagnosis, in this importa and common type of case, between "abdomi migraine," gastric influenza, acute food poisoni gall-stones, and chronic cholecystitis. The gall-bladd has frequently been blamed for these attacks, but t results of cholecystectomy have in many instan been disappointing. McClure and Hunting analysed a group of cases of "abdominal migraine in six such patients, whose gall-bladders were remov for organic disease, the headache was unaffected b the operation.

Estimation of the efficiency of liver function undoubtedly difficult, and there is consider variation in the results of these tests in this type case. Nevertheless, there would seem to be a c siderable amount of evidence pointing to li dysfunction as the initial cause, and Hunt sugg that in many of these cases the primary lesion i subacute hepatitis, resulting from absorption toxins or bacteria from the intestinal tract (e colitis or appendicitis) or other areas of infecti such hepatitis may allow the passage of orga into the gall-bladder causing chronic cholecy or the formation of gall-stones, and may be unaffe by the removal of the diseased gall-bladder u the source of infection is also attacked. He q an interesting and suggestive case in which ch cystectomy and many other forms of treatment ough he had demonstrated anatomical facts to pport his contentions, when actually such is not the se. Quite apart from the lack of evidence, this pothesis is unconvincing, and any theory based on raised intracranial tension seems to be conidicted by what we know of the cerebro-spinal fluid essure in migraine.

---

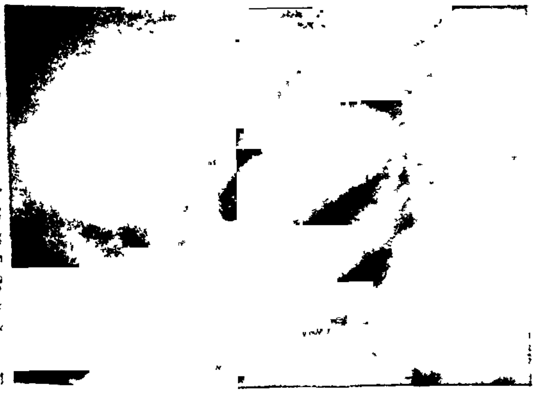
* The opening paper at a discussion at the Harveian So on Dec. 8th, 1932.

THE ENDOCRINE FACTOR

Almost all the endocrine organs have been blamed one time or another for attacks of migraine. The sociation on the one hand with hyperthyroidism, with hypothyroidism on the other, has led to ray treatment of the thyroid or to the use of ugol's iodine or thyroid extract. Hartung[18] has ported cases in which the attack was invariably it short by an injection of adrenaline. The relation tween migraine and the ovarian and pituitary cretions is probably more important. The frequent nset at puberty, the intimate relationship with the enses in many cases, and the marked diminution the attacks after the menopause or during pregnancy re all cited as factors in favour of an endocrine igin.

An abnormal inter-relation is often postulated tween the thyroid, pituitary, and the sex glands, nd on this theory migraine has become easy game r the pluriglandular therapists. They have not ways been discrete or scientific in their use of their roducts or their claims, and have thus brought ndocrine therapy into disrepute. Jelliffe sums up e position in a nutshell when he says: "Naturally e endocrines cannot be neglected—various authors mplicate now this, now that, and usually have three r four balls in the hypothetical endocrine air and ot all gonads."

FIG. 2



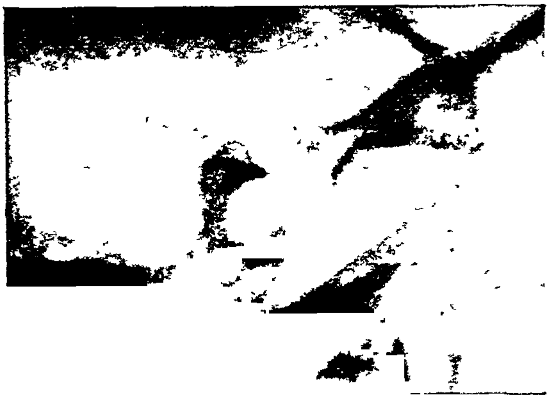
very good example of a "bridged-in sella" from a man of 23. who gave a history of six epileptiform attacks, but an otherwise normal previous history, and no account of periodic headaches.

In migraine cases showing an intimate relationship ith the menses, Hartung[18] has recommended ypodermic injection of anterior and posterior lobe ituitary extract or of whole-gland extract twice a eek for the first month and thereafter once weekly, nd, in addition, oral administration of the whole owdered gland (gr. 1/20–½). Treatment has been ontinued for three to four years.

On the grounds that many cases of migraine are ue primarily to ovarian dysfunction, Blackie and ossack[19] have treated several cases of "menstrual igraine" with Collip's placental hormone—Emmenin omplex (Glaxo) ½–1 drachm twice daily, except uring the menstrual period. Although their line of treatment was empirical, yet we have found it successful in "menstrual migraine."

Recently A. P. Thomson[20] has reopened the problem of intermittent headache occurring particularly at menstruation, and its association frequently with radiological abnormalities in the sella turcica, as originally suggested by Timme. He would prefer to regard his cases as different from typical migraine, and emphasises that few were able to localise the headaches, which were never unilateral and never of the expanding type of "classical migraine." For the reasons which we have given in discussing the clinical aspect we feel that we must regard them as migraine variants—"menstrual migraine." Moreover, out of his 25 cases, 10 developed similar headaches at irregular intervals as well as at the menstrual periods.

FIG. 3



The sella turcica in a man of 47, suffering from traumatic neurasthenia. No history of headache.

Thomson suggests that, owing to abnormal ossification around the pituitary body or to unusual development of the diaphragma sellæ, the pituitary body is enlarging in a limited space and therefore gives rise to severe headache. Radiological abnormalities in the sella turcica were demonstrable in 17 out of 25 cases, the most common abnormality being ossification of the interclinoid ligaments.

The work of Aschheim and Zondek and others has demonstrated quite clearly the relation between the activities of the ovary and the anterior part of the pituitary body. Hormones elaborated by the basophilic cells of the anterior pituitary stimulate the ovarian follicles and determine the function of menstruation. Experimentally it is shown that the administration of the ovarian follicular hormone causes a diminution in the activity and size of the pituitary, and the results of treatment by such hormones have been remarkably successful in Thomson's cases and in others of our own. He recommends that three injections of theelin 1 c.cm. (50 rat units each) should be given in the week before the period is due, but when the headaches occur at irregular intervals as well as at menstruation, two to three injections of 50 units should be given regularly each week. It seems possible that it will not be necessary to continue the treatment (there is often unfortunately some local pain for two to three minutes after the injection) throughout the patient's menstrual life. Although we can endorse the therapeutic value of an active ovarian follicular hormone in these cases, yet we dislike the view that the headache is due to pressure of the swollen pituitary body against another case, recorded by Lubbers,[9] the migraine attack occurred only after eating beans. After a test-meal of beans the leucocytes immediately diminished in number and migraine developed eight hours later. Skin tests were negative; preventive ingestion of 0·5 g. of peptone before eating the beans warded off the migraine, though the patient felt chilly and drowsy.

Thus the treatment of migraine due to food allergy is carried out by "elimination dieting," modified according to the suspected factor.

Rowe[10] has done a considerable amount of work in support of the above views, and Balyeat and Brittain[11] consider that the exciting factor in migraine is probably always a specific sensitivity to one or more foreign proteins, and they would regard physical and mental fatigue as predisposing factors.

VASOMOTOR AND SYMPATHETIC TYPES

Allied to the above is the *vasomotor type*, in which it is held that the migraine is the result of a localised intracranial œdema. Erythromelalgia, attacks of angioneurotic œdema, orthostatic albuminuria, and syncopal attacks were all present in association with typical migraine in a patient recently under observation. Treatment with full doses of calcium lactate or calcium subcutaneously produces good results in such cases. In this connexion it is interesting to recollect the popular treatment for the headache of "the morning after the night before" by calcium lactate.

At this point it will be convenient to refer briefly to the *sympathetic* type. Acting upon the supposition that migraine was dependent upon an excessive stimulation of the sympathetic and a resultant spastic contraction of the cerebral arterioles with subsequent relaxation, an attempt was made to control such vasospasticity by the use of a sympathetic depressor—ergotamine tartrate (2 mg. by mouth). Tzanck, Trautmann,[12] Targhetta, Ignelzi[13] have reported very encouraging results from this treatment. Irradiated ergosterol and calcium therapy were employed in addition, in order to increase the threshold of resistance to sympathetic irritability and to render the migraine attack more amenable to treatment by the ergotamine tartrate.

Dandy[14] has attempted to achieve the same object surgically by removal of the first thoracic sympathetic and inferior cervical ganglia. The results were encouraging, but he preferred to reserve his opinion as to the absolute value of the procedure.

SOME OTHER TYPES

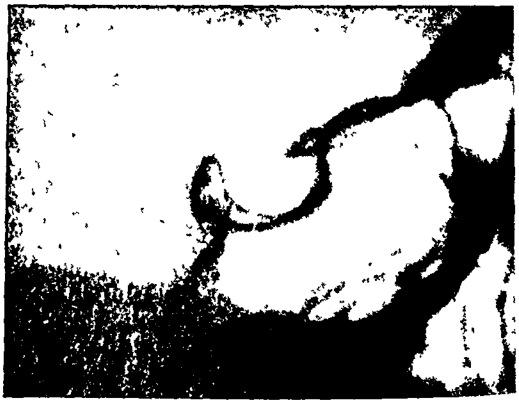
Before discussing the inter-relationship of the endocrine organs, the autonomic nervous system, and migraine, we will refer briefly to the ocular, sinus, fibrositic, para-epileptic, and cerebral types.

Some reference has already been made to the *ocular* type. There is still much difference of opinion as to the importance of the rôle of errors of refraction and slight muscle-balance defects. It is suggested that eyestrain increases the irritability of the central nervous system and thus produces migraine. In the Savill lecture in 1924, Hurst[15] stated the case in favour very ably and strongly; recently Elliot[16] has stressed the significance of ocular abnormalities. Although there are undoubtedly many cases in which the visual apparatus is primarily at fault, and in which migraine is cured by correction of refractive errors, &c., yet we feel that the importance of this factor has been over-estimated.

Whatever the relative importance of the part played by the eyes, it is obviously our duty to see that no person is allowed to remain for years an unrelieved migrainous subject without careful ocular tests and correction along the lines indicated by Elliot.

There are a certain number of true migraine cases with well-marked *sinus disease*, in which the treatment of the sinus lesion has led to cure of the migraine. The association of migraine or migrainous neuralgia with non-articular rheumatism, brachial neuritis and scalp tenderness in an attack, separates off a further group—the *fibrositic* type. This group should be treated by salicylates, physiotherapy (ionisation) or the local injection of Impletol (a complex combination of a local anæsthetic with caffeine prepared by Bayer). The true cases of migrainous neuralgia respond to alcoholic injection of the Gasserian ganglion or its branches.

FIG. 1



Radiographic appearance of the sella turcica in a normal subject

The similarity in many respects between migraine and epilepsy and their occurrence in the same patient has led to the separation off, from a pathogenic and therapeutic point of view, of a *para-epileptic type*. The knowledge of this relationship led to treatment of migraine by bromides, luminal,[17] and the ketogenic diet.

Certain cases of typical migraine result from macroscopic intracranial lesions constituting what might be conveniently referred to as the *cerebral* type. In one of our series an occipito-parietal angioma was found, and Collier records a similar case with typical monthly attacks of migraine of three years' duration. The patient died suddenly, and a tumour was found in the convexity of the occipital lobe, corresponding to the field in which the visual phenomena were wont to appear. Further, apparently typical migraine attacks occur in patients who have died later of a ruptured congenital cerebral aneurysm. This association has been observed and reported too frequently to permit of its dismissal as a coincidence.

Here we might conveniently refer to the much quoted hypothesis of Spitzer. This author suggested that a congenital stenosis of the foramen of Munro forms the substratum of the migraine constitution. During an attack the foramen becomes plugged by a tag of congested choroid plexus; in this way the intracranial tension is raised, temporary internal hydrocephalus results, and pressure of the cerebral cortex against the unyielding dura causes first the premonitory symptoms and later the headache. Although this speculation has received considerable notice, we must bear in mind that it is purely a hypothetical conception. Spitzer is often quoted as

Between the attacks some of the cases may suitably be treated with magnesium sulphate, glucose and bile acids, theelin, thyroid, special diet, or psychotherapy. The remaining group of migraine cases, which we are unable to place in a special category, must be regarded for the present as idiopathic, and treated with one of the following:—

(1) Luminal, gr. ½–1 bis die.
(2) A prescription similar to Gowers' mixture:—
R

Sod. brom.	gr. x.
Liq. trinitrin	♏ i.
Liq. strych.	♏ v.
Ac. hydrochlor. dil. ..	♏ x.
Tinct. gelsem	♏ v.
Aq. chlorof. ad ℥ ss. ..	℥ ss. ter in die post cibos,

or R

Ext. thyroid	gr. ½ three times daily.

For the very severe cases which do not respond to any of the above measures we would recommend a right subtemporal decompression. Gordon Holmes says that he has never known migraine persist in a patient who has had a surgical or traumatic decompression.

Therapy is undoubtedly difficult in such a polymorphic disease, but we must not allow ourselves to become despondent, despite the importance of the hereditary factor and the migraine constitution.

The expenses of this investigation were defrayed by the Medical Research Council.

OBSERVATIONS ON GALL-STONE CASES

By E. R. Flint, M.B. Leeds., F.R.C.S. Eng.

HON. SURGEON WITH CHARGE OF OUT-PATIENTS, GENERAL INFIRMARY, LEEDS

GALL-STONES are formed for the most part in the gall-bladder, either as a deposition from the bile in some metabolic disturbance or secondarily to cholecystitis, however that may be produced. When they are found in the common duct they have usually passed into it from the gall-bladder, but in a small proportion of the cases they either come direct from the liver or are formed in the common duct itself. Those which come from the liver are bilirubin stones and splenectomy may be required to prevent recurrence; those which form in the common duct appear as a result of cholangitis, past or present, and may be single or multiple, are often quite large, contain little if any cholesterin, and crumble easily. An appreciable amount of cholesterin is evidence of formation in the gall-bladder. If symptoms of a stone in the common duct recur, the most usual cause is that the stone was overlooked at the first operation.

The relative frequency of stones in the gall-bladder to stones in the common duct coming to operation is about 15 to 1, and though circumstances may render gall-bladder stones and their treatment a danger to the patient, stones in the common duct are certainly a greater menace to life and present more difficult problems to the surgeon.

The success of operations on the common duct depends very largely, in my opinion, on pre-operative preparation against those factors which are responsible for the deaths. It is not always easy to be sure of the real cause of death, but in 75 post-mortem examinations made during six years on patients dying in the Leeds General Infirmary after operations on the biliary passages the prominent features were:—

1. Peritoneal sepsis—mostly local, sometimes general	27
2. Broncho-pneumonia (without peritonitis)	17
3. Cholangitis	10
4. Myocardial degeneration	10

In these 75 cases the operation performed and the cause of death given (tabulated as above and in the same order) were:—

Cholecystectomy (36)		Cholecystotomy (17)		Choledochotomy (22)	
1.	14	1.	8	*1.	5
2.	9	2.	4	2.	4
3.	2	3.	1	3.	7
4.	3	4.	2	4.	5

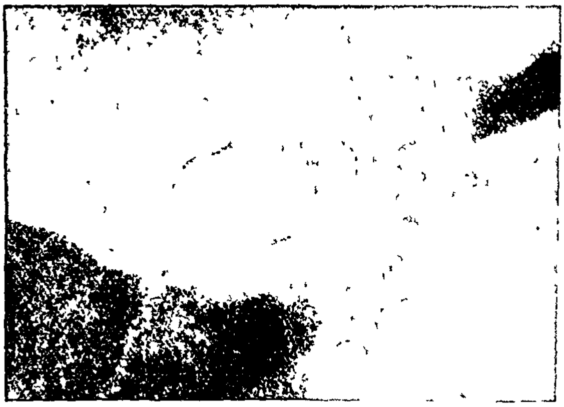
* Four of these had a gall-bladder operation at the same time.

In many of the cases there were multiple findings at autopsy—e.g., toxic changes in the heart, liver, kidneys, and lungs were not uncommon in the cases with peritonitis, as would be expected, but so far as possible the causes of death here given show the primary lesions. Broncho-pneumonia, for example, is only given separately when it was not accompanied by acute infection elsewhere. Again, myocardial degeneration is given as the cause of death only when it was the predominating lesion, but some defect in the heart muscle was quite common, and it is impossible to exclude its influence in some of the broncho-pneumonic cases. Bearing in mind these limitations and the fact that the number of post-mortems is small, yet some interesting features are revealed.

PERITONITIS

The predominating cause of death is peritonitis—usually local, occasionally general. It accounts for more than a quarter of the total mortality. A degree of local peritonitis is a necessary reparative process, and possibly some reduction should be made to allow for the pathologist's over-statement on this account. But where there is a suppurative peritonitis (as in practically all the cases here reported) it should be regarded as a pathological lesion. It is well known that acute infective processes in the gall-bladder can be trusted to remain localised; we feel so confident of this that a policy of operative delay is deliberately taught and practised. The delay is usually a matter of a week or so, by which time the acute symptoms have subsided. At this stage it is common to find considerable peritoneal injection, if not actual pus, around the gall-bladder. This is especially the case when a stone is impacted in the neck of the gall-bladder, the type of lesion which accounts for most of the cases coming under the heading of acute gall-bladders. In fact, there is a state of affairs resembling very closely the acute obstructed appendix; in both cases perforation is a the abnormally ossified sella turcica or an unusually well developed diaphragma sellæ. It is, of course, extremely difficult to deny a factor of compression against the diaphragma sellæ, but we feel fairly certain that the abnormal ossification as seen in the "bridged-in sella" does not cause compression of the pituitary body. There is ample space laterally for the pituitary to enlarge, and if the sellar tension was raised to the extent which is suggested we might reasonably expect some ballooning of the sella. Thomson mentions his failure to demonstrate the "bridged-in sella" in individuals who do not complain of headaches.

FIG. 4



An almost completely "shut-in sella" in a woman of 32, who had suffered from migraine-epilepsy for many years. There was no relation between the attacks and the menstrual periods.

We, however, have collected several cases of "bridged-in sellæ" from patients who have never suffered from migraine (Figs. 2 and 3). It appears then that such radiological abnormalities are found in patients of either sex without any history of headaches, and also in cases of migraine or intermittent headache not of the menstrual type (Fig. 4), and we have a patient closely resembling Thomson's cases, in respect of the relation to the menses, who has an almost completely "shut-in sella" and yet gives a history of typical migraine attacks in addition to the menstrual headache (Fig. 5). This case seems to argue in favour of our view that the intermittent headache referred to by Thomson is a migraine variant. *We propose to deal more fully with this interesting problem in a subsequent paper.*

PSYCHOLOGICAL ASPECTS

As we have pointed out in discussing the migrainous constitution, there is no doubt that in many cases the psychological factor is of considerable importance. True attacks of migraine are very frequently encountered in association with mental overwork, anxiety, or "suppressed rage and humiliation." We have one patient who said that, by allowing himself to get very annoyed and "worked up," he could almost "throw himself" into an attack. Hilda Weber[21] has recently discussed very fairly and clearly the psychological factor in migraine, and reported a case in which a migraine attack was a means by which the unconscious found expression.

> The main purpose underlying the attack "was the preservation of the infantile narcissism and the connected feelings of omnipotence." From earliest years this patient by her migraine had achieved a two-fold end; it not only kept her at home but it *also enabled her to make an otherwise harsh and tyrannical mother her slave.* During the attacks she became the centre of the family attention, and this in itself must have gone far to compensate for the pain which she suffered. Much as she disliked physical discomfort she hated still more the pangs of thwarted self-love.

Excellent results followed psychotherapy, and without in any way exaggerating the importance of the psychological factor, it seems clear that other cases like the above will respond to psychotherapy when other means will fail.

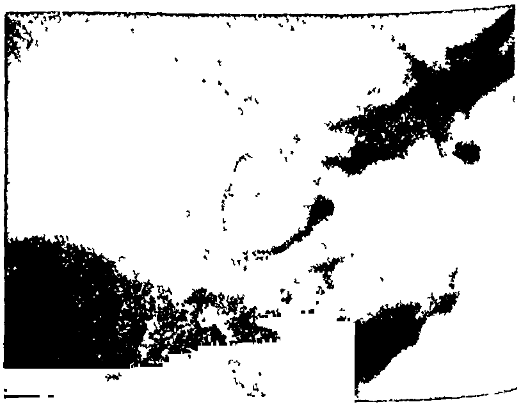
Conclusions

Ætiology.—Migraine is obviously a complicated *and difficult problem, and despite an immense* amount of research the essential causation still remains obscure. It seems certain, however, that there must be at least two factors, "central" and "peripheral." In the present state of our knowledge any view must be speculative, but we are inclined to regard migraine as a vasomotor manifestation associated with spasm of the cerebral arteries—most commonly branches of the internal carotid—due to stimulation of sympathetic fibres, either as the result of direct pressure or via the endocrine system, occurring in a susceptible person with the migrainous constitution and with precipitating factors—metabolic, alimentary, ocular, sinus, &c.

Investigation.—Success in treatment will depend on ability to place a particular case of migraine in its proper category and apply the appropriate remedy. It follows that the complete investigation of a patient with migraine will include :—

(1) Careful previous and family history and a minute study of the symptomatology.
(2) Physical and psychological examination.
(3) Careful testing for ocular abnormalities.
(4) Radiological examination of sinuses, sella turcica, gall-bladder, and gastro-intestinal tract.

FIG. 5



The sella turcica in a woman of 47, having severe migraine attacks (with visual phenomena), occurring chiefly at the menstrual periods but not invariably so.

(5) Full examination of the cerebro-spinal fluid, including pressure readings.
(6) Biochemical investigations (blood-sugar estimation, urine, alkali reserve).
(7) Basal metabolic rate investigation.

Treatment.—It is customary to discuss the treatment of migraine under two headings: (*a*) in the *attack, and* (*b*) *between the attacks. In the former* it is useless trying to "fight off an attack," and we would recommend retirement to a quiet darkened room as soon as possible, and the administration of one of the following :—

(1) Veramon grs. 6—repeat in half an hour.
(2) Phenacetin grs. 15 and caffein. cit. grs. 5, to be repeated, if necessary, at hourly intervals for three doses.
(3) Compral, 3 tablets every six hours.

which threaten patients with stone in the common duct—viz., hepatic failure and post-operative hæmorrhage.

THE HEART

The post-mortem findings in the heart are myocardial degeneration in some 22·8 per cent. of common duct cases and about 7 per cent. of gall-bladder cases. It is difficult to be sure of the significance of this observation, since some myocardial defect is so commonly seen in many gall-stone cases. But so far as I can judge from the available evidence, the greater frequency in common duct cases is related in some way to the presence of jaundice. Retained biliary products have a definitely toxic effect on the parenchymatous tissue of organs; this is seen clinically in the kidney, where deep obstructive jaundice is sometimes associated with albuminuria and a high blood-urea. Experimentally, intraperitoneal injections of bile are fatal to rabbits, and intravenous injections are fatal in even small doses. Death results from changes in the myocardium, where necrosis is produced, and severe degeneration is also found in the kidneys and liver. The heart is perhaps peculiarly vulnerable in these circumstances in the human being because of the prevalence of fatty infiltration in obese subjects.

PRE-OPERATIVE TREATMENT

It is seldom necessary to rush operation in common duct cases; and I believe that preparation for operation is a very vital factor, and one which does not receive the attention it should. Consequently the total mortality of common duct calculus cases is reported as being in the neighbourhood of 15 per cent. My own mortality is 7·5 per cent.; 4 per cent. in private patients and 10 per cent. in hospital cases. I feel confident that this has been achieved very largely through careful, and sometimes long, preparation.

In addition to the ordinary medical care of the [illegible] of which rest in bed is perhaps the most [illegible] the methods employed before operation (and they may be needed afterwards as well) are as follows:—

1. *Water.*—This should be given very freely, because dehydration is not uncommon in jaundiced patients, and also it flushes the kidneys and so tends to remove the renal threat, which is a real one in many cases. If the common duct is drained to the surface as much as 1500 c.cm. of fluid may be lost in 24 hours; this can be prevented to some extent by using a T-tube.

2. *Glucose.*—This is essential and may be given by any route along which absorption is certain. Repeated or continuous intravenous injections seem to be most effective, and 10 per cent. glucose and 1 per cent. saline solutions should be used. In addition to being an easily assimilated form of food, it seems to have an especially beneficial effect on the liver and kidneys.

3. *Calcium.*—If there is reason to suppose there may be post-operative bleeding, 5 c.cm. of 10 per cent. calcium chloride is usually given on three consecutive days; I am not at all sure that calcium chloride is reliable, and I much prefer one or more blood transfusions. In addition to an efficient anti-bleeding effect these supply a vitalising factor of great potency, and are therefore useful even when post-operative hæmorrhage is not anticipated.

SURGICAL TECHNIQUE

Most anæsthetics damage living cells, and it is necessary to choose that one which produces the least insult to the liver, particularly in common duct cases. I have no doubt in my own mind that spinal anæsthesia best fulfils the conditions. It has other great advantages but some drawbacks, the chief of which lies in getting it to the right level. This is largely a matter of attention to detail and accustoming oneself to the behaviour of one of the many techniques from which a choice may be made.

Owing to the remarkable variation in the anatomical arrangements of the bile-ducts and the hepatic and cystic arteries, some of which I have described,[3] there are perhaps more traps for the unwary in the surgery of this region than in any other, and it is therefore of the utmost importance that nothing be divided that has not been clearly identified. This should be a very obvious principle, but it is by no means always applied; it requires not only *unremitting care and infinite patience* to define the essential structures, often in trying circumstances, but also great gentleness, as the parts are highly sensitive to manipulation.

It is especially important to prevent chilling of the portal blood in common duct cases. Crile applies diathermy to the external surface of the body over the liver; I have no experience of this, but have used hot applications, and by means of thermometers inside the abdomen I have not been able to detect any material rise in temperature. The most practical method is the use of hot moist intra-abdominal packs, as is the usual practice, but extra precautions should be taken to keep these warm and to prevent the exposure of viscera.

With adequate pre-operative preparation it is usually safe to remove stones from the common duct and perform cholecystectomy (since the bladder in these circumstances generally needs removal) at the same time, but occasionally the patient is so ill with cholangitis that drainage of the common duct is all that is permissible; the stones can be dealt with at a subsequent operation.

When operating for a supposed *stone in the common* duct careful palpation may fail to detect one; is it necessary to open the duct and explore from the inside to make sure? Generally I should say no, but there are occasions when I believe it is impossible to be sure without open exploration:—

1. When the head of the pancreas is thickened and hard. It is easy to miss a stone in these circumstances, especially in the region of the ampulla.

2. When the common duct has lost its normal bluish colour, and is rather thickened and dilated. Dilatation with a contracted gall-bladder is usual and does not necessarily mean obstruction, but if there has been jaundice one should make absolutely certain the duct is clear, and this may be impossible with a small stone without opening the duct. It is as well to remember in this connexion that some 25 per cent. of patients with stone in the common duct have never had jaundice and about 5 per cent. do not give a history of pain.

The post-mortem records are interesting in that stones were found in the common duct in 6 out of 33 cases dying after cholecystectomy, no operation having been performed on the common duct. Stones were found at autopsy in the common duct in 3 out of 22 cases dying after choledochotomy. These cases are not quite so convincing as the first series, since the notes gave no indication whether the duct was intentionally merely drained.

When there is a stone in the lower end of the common duct it is better to remove it through the duodenum than to make a prolonged effort to get it into the supra-duodenal portion. Trans-duodenal choledochotomy certainly has no greater mortality than common complication, but there is this difference—in the former we know that the mischief will be localised, in the latter we fear it will not be. In the first case we wait; in the second we operate at once, and in both instances we are pretty sure the patient is safe, at any rate, for the time being. Why, then, should there be such a large percentage of peritonitis in the mortalities which follow gall-bladder operations? I believe it is due to one of two reasons (I exclude introduction of organisms from outside; this surely cannot be a factor in these days):—

1. The infection is not localised so readily as we think; this seems an unlikely explanation since general peritonitis is not common with acute gall-bladder infections.

2. Operation is performed at the wrong time. It is customary to wait a week or so for symptoms to subside and then to operate. Usually, of course, things go all right, but sometimes there is still active inflammation, and perhaps pus; then the size of the wound and the manipulation necessary to do what is required must disseminate the infection rather widely, into freshly opened-up local areas, or even into the general peritoneal cavity. What should we think of a surgeon who made such inroads in the presence of a persisting infection around the appendix?

That this is probably the true explanation is supported by the figures of fatal peritonitis following gall-bladder operations as compared with those of common duct operations, where a really active pericholangitis is rarely seen—41·5 per cent. as against 22·8 per cent. (5 in 22 autopsies after a common duct operation; in 4 of these the gall-bladder was removed at the same time).

The practical inferences to be drawn seem to be: either to operate on the acute gall-bladder at once, as we do on the appendix (the cases I have treated in this way have done very well), or to leave things to settle much longer than is the custom at present. The thing to avoid is operation during the stage when active pericholecystitis may still exist.

FATAL LUNG COMPLICATIONS

In the absence of a local suppurative condition these follow any of the three operations with about the same frequency. When suppuration is present the lungs are involved in most cases, but not more often, I think, than we expect to see after operations on suppurative lesions anywhere. Lung complications, not necessarily fatal, are seen, I believe, more frequently after gall-bladder operations than after most other intra-abdominal manœuvres, partly because of the technical difficulties in a very sensitive field so near the diaphragm, and partly because obesity renders these patients peculiarly vulnerable. Most gall-stone patients are fat, and the difficulties of operation are thereby increased. But excessive fat increases the risks to the patient in other ways too. Fatty tissue has a low resistance to infection, and where the common duct or gall-bladder contain organisms there is apt to be some infection in the wound. This in itself is not likely to be serious, but more retraction is necessary than in thinner patients in order to expose the essential parts, and this makes breathing more painful afterwards. Large or small areas of atelectasis are apt to be induced thereby, and this, together with the low-grade infection in the fatty wound, may determine the onset of septic broncho-pneumonic areas. Infarcts of the lung are more common, too, in fat patients; possibly these two conditions are one and the same, but I think not. There are reasonably reliable tests of function of some organs to inform the surgeon whether the organs are capable of doing what they will be called upon to do, but with the lungs it is different; we rely on the ordinary clinical examination for evidence of reasonable soundness and virtually know very little about their vital capacity. I admit I do not see quite how we should proceed in this matter, but there are certain physiological methods which might be applied and give us a better understanding of the functional efficiency and elasticity, so to speak, of these organs under stress. The empirical use of carbon dioxide has done a good deal, I think, to lessen undesirable lung complications.

CHOLANGITIS

Cholangitis is the cause of death much more frequently after common duct operations than after those on the gall-bladder—31·8 per cent. against 5·5 per cent. It is many years since E. V. Graham[1] pointed out that hepatitis is a more or less constant factor in cases of cholecystitis, and I have corroborated this,[2] and at the same time shown some apparent connexion between the degree of hepatitis and the results of the van den Bergh and lævulose-tolerance tests. The lesion is a pericholangitic small-celled infiltration, sometimes with fibrous and fatty changes. Interpretation of the hepatitis differs, but it is agreed that the condition is most advanced in the common duct cases, leading in extreme instances to intra-hepatic abscesses. The damage to the liver is caused either mechanically by back pressure, often associated with sepsis, or by poisoning of the parenchyma by the retention products carried in the blood stream, whatever the nature of these may be. The cause is probably not bilirubin itself, but bilirubinæmia has considerable practical interest; it acts as an indicator, giving information of what is occurring in the liver, rather as urea in the blood does for the kidneys in prostatic enlargement. In either case the rise is due to retention, and indicates damage to the organ involved. In such circumstances we should do a two-stage operation for prostatic enlargement, and the same principle applies to common duct obstruction due to stone; but there is this difference: in the former instance we have to relieve the back pressure by surgical means, whereas in the latter it is done by Nature if we will have the patience to wait, since it is rare for a stone completely to block the common duct for long.

The dangerous periods, so far as the liver is concerned, are during the time the bilirubin curve is rising rapidly, which it does when the duct becomes suddenly blocked, and when the curve is rising gradually and continuously to a high level, as in malignant obstruction. In the first case the wise course is to wait for a falling curve, which will almost certainly appear in quite a short time, and in the second (if any operation is to be performed) not to delay too long, for a remission of the jaundice is most unlikely.

It is only possible to be sure of the state of affairs by doing repeated van den Bergh tests, because there is a rising curve for bilirubin in the blood before jaundice reveals itself clinically. The van den Bergh reaction in this obstructive type of jaundice is, of course, always of the prompt direct variety. The trouble with hepatic tests is that, though they may give evidence of liver inefficiency, they are not able in most instances at present to demonstrate the degree of injury. But if we look upon hyperbilirubinæmia as an indicator of some hepatic damage, in the same way as we do high blood-urea in kidney conditions, and deal with it on similar principles, I think we shall do much to ward off two of the factors o definite proof exists of the nature of the infecting rganism. The fact that *B. dysenteriæ* Sonne was solated from a sister who had been ill at the same time s Case 4 makes it likely that in this case, at any rate, he infecting organism was of the Sonne type.

In 1926 Fraser, Kinloch, and Smith [2] reported an utbreak of dysentery in Aberdeen. In 1929 Charles nd Warren [1] recorded a similar outbreak in Newcastle. Various other writers have described maller epidemics. The attention of this department was directed to the matter by an outbreak in the children's ward of the Royal Hospital in 1928, and since then there have been two smaller outbreaks. In spite of the attention that has been drawn to epidemics of bacillary dysentery in the last few years, there does not appear to be general recognition of the fact that the disease is endemic in this country.

It is well recognised that in certain cases of Shiga and Flexner infection the toxæmia may be so everwhelming as to bring about a very early fatal termination. Charles and Warren have recorded several cases of the sort, but the Sonne bacillus has in the past usually been regarded as only mildly toxigenic. Fulminating infection with rapid death due to *B. dysenteriæ* Sonne, as in Case 4, does not appear to have been reported before. That death should occur as the result of a dysenteric infection without the appearance of the cardinal symptom of diarrhœa, as in Cases 1 and 2. does not seem to have been previously noted. This possibility should be borne in mind in cases of sudden death in children.

The post-mortem examinations on all the cases recorded were made by Dr. S. C. Dyke, pathologist to the hospital, at the instance of Mr. J. T. Higgs, coroner for South Staffordshire, and of Mr. A. C. Skidmore, coroner to the borough of Wolverhampton. I am indebted to the coroners concerned for permission to publish the cases; to Dr. D. E. S. Cunningham, of Upper Gornal, for material; to Dr. M. W. Wallace, of Wolverhampton, for the history of Case 3; and to Dr. Dyke for access to his notes and for advice and assistance.

TUBERCULOUS LARYNGITIS:

THE IMPORTANCE OF EARLY DIAGNOSIS

By Harold Barwell, M.B. Lond., F.R.C.S. Eng.

CONSULTING SURGEON FOR DISEASES OF THE THROAT AND EAR,
ST. GEORGE'S HOSPITAL; LATE LARYNGOLOGIST, MOUNT
VERNON HOSPITAL FOR DISEASES OF THE CHEST

Tuberculous laryngitis is pre-eminently a disease in which early diagnosis is all-important for successful treatment. As it is, with exceptions so rare as to be negligible, a complication of pulmonary tuberculosis, it can normally be recognised early if it is looked for; and I wish here to urge again, as I have done for over 25 years, that all phthisical patients must have their larynges inspected at regular intervals of a few months, whether or not they have symptoms referred to the throat, and that they be sent to a laryngologist if this complication cannot be excluded with certainty. A good many consumptives suffer from hoarseness, or have a characteristic weak voice; this is often merely the result of asthenia, but these patients also have an unusual tendency to attacks of simple laryngitis, partly from the strain of coughing and partly from infection by secondary organisms in the sputum. On the other hand, a tuberculous lesion, perhaps in the posterior commissure or at the upper aperture, does not necessarily cause any symptoms in an early stage, and the disease can, therefore, neither be diagnosed nor excluded by the patient's symptoms alone, but only by laryngoscopy.

Invasion of the larynx is usually the result of the entrance of tubercle bacilli contained in the sputum directly through the epithelium, and takes place most often in the neighbourhood of the vocal process where the mucosa is thin, closely applied to the cartilage, and liable to abrasion from coughing. The earliest lesions are, therefore, most often found at the level of the glottis and tend to spread from behind forwards along the vocal cord, or backwards to the posterior commissure. The upper aperture is seldom involved before the glottis, although not infrequently swelling of the arytenoids is the first lesion to attract attention, and the epiglottis is rarely attacked until the rest of the larynx has been extensively affected. It is often said that pallor is a characteristic feature of tuberculous laryngitis, but this is only partly true. Many consumptive patients are anæmic, and then the larynx, together with the other mucous membranes, will also be anæmic; in other cases the colour is normal or reddened from coughing and irritation by the sputum. Tuberculous granulations are usually pallid, the margins of ulcers are not hyperæmic, and arytenoid infiltrations are pale; but the unaffected portions of the larynx have no characteristic colour, and very often tuberculous infiltration on the cords, ventricular bands, and especially on the epiglottis, has a deeply congested red coloration. Granulations are typically of a *soft*, gelatinous appearance; when healing occurs there is but little fibrosis or deformity, in contradistinction to the lesions of syphilis or lupus, and stenosis causing dyspnœa is extremely rare.

CLINICAL VARIETIES

As any part of the larynx may be affected, the clinical picture is very variable, but for the sake of clearness five types may be described.

1. In the "chorditic" type the vocal cords are principally affected, and hoarseness and aphonia are early symptoms. The lesions are seldom symmetrical. Swelling and redness confined to one cord is not due to simple laryngitis; it may be caused by traumatism,

the more usual operation and has the advantage that bile flows into the intestine instead of to the surface. It has this further point in its favour: if no operation is performed on the gall-bladder at the same time the wound may be completely closed, whereas such a piece of technique after supra-duodenal choledochotomy is very risky.

During the final stages of any operation 10 per cent. carbon dioxide in oxygen is given, and this is repeated for ten minutes in each hour for several hours after the patient has returned to bed. I think two good effects are promoted by this: first, the lungs are more fully inflated by the deeper breathing, and atelectasis (which is probably the beginning of much post-operative chest trouble) is discouraged; secondly, better oxygenation of the blood is provided. I think there is no doubt that anoxæmia is responsible for some of the fall in blood pressure which follows many anæsthetics and particularly spinal administration. In addition, many of the special methods employed in pre-operative preparation should be carried on in the after-treatment as a routine.

DYSENTERY AS A CAUSE OF SUDDEN DEATH

By Eileen Harvey, M.R.C.S. Eng.

ASSISTANT PATHOLOGIST AND MEDICAL REGISTRAR, THE ROYAL HOSPITAL, WOLVERHAMPTON

That dysenteric infection may prove rapidly fatal, so rapidly in fact that in certain cases there may not be time for the development of any symptoms of the disease, does not seem to have been previously noted. The following cases are recorded with a view to drawing attention to this point. Every case was the subject of a coroner's inquiry. In two of them death occurred suddenly, and no cause was apparent before the post-mortem examination; in the remaining three it was evident that some form of intestinal infection was the cause of death.

CASE RECORDS

Case 1 (male, aged 9 years) retired to bed, apparently in normal health, but woke up at 3.30 A.M., vomited copiously and died within one and a half hours.

At *post-mortem* examination the body was that of a well-nourished male child. The cranial and thoracic cavities showed nothing abnormal. The spleen was rather enlarged and firm in consistency, and on section the cut surface showed numerous white dots marking enlarged and probably necrotic Malpighian corpuscles. The stomach contained some clear yellow fluid; the mucous membrane appeared healthy. The whole of the small bowel from the jejunum downwards contained a great deal of thick mucus. In the ileum the Peyer's patches were prominent and showed evidence of early necrosis of lymphoid elements; towards the lower end of the ileum small patches of lymphoid proliferation in the mucosa became evident; these increased downwards until the last few inches before the ileocæcal valve were thickly studded with them, and at the valve itself there was a definite ring of lymphoid proliferation and hyperplasia. This hyperplasia diminished rapidly from the valve downwards; the lower part of the large bowel was filled with liquid fæces.

Case 2 (male infant) appeared well when he was put to bed but was found dead a few hours later.

At *post-mortem* examination the body was that of a well-nourished infant; there were small petechial hæmorrhages scattered over the face and neck. The brain substance was soft. The heart and lungs were normal. In the abdominal cavity there were numerous enlarged soft mesenteric glands. The spleen and liver appeared normal; the kidney showed cloudy swelling. Nothing abnormal was seen in the stomach, duodenum, or jejunum. The ileum showed increased prominence of Peyer's patches from above downwards; towards the cæcum there was evidence of early ulceration. In this area the mucosa was covered with closely packed white nodules of hyperplastic lymphoid tissue, and these formed a definite ring around the ileocæcal valve. The whole of the large bowel showed intense proliferation of the lymphoid elements, which appeared as prominent white dots. The lower bowel was filled with liquid fæces.

Case 3 (male, aged 3 years) appeared well when he went to bed; he woke up at 6 A.M., vomited once and passed a loose stool with no obvious blood; diarrhœa continued until midday. The temperature was 101°–103° F., but his condition did not cause his doctor anxiety until the evening, when he became very collapsed and died at midnight.

At the *post-mortem* examination he was a well-nourished male child. The small bowel contained yellowish fluid fæcal matter, and the lower part of the large bowel was ballooned out with a large liquid stool containing mucus but no blood. Peyer's patches throughout the ileum were very prominent but showed no signs of necrosis; the mucous membrane of the lower few inches of the ileum and cæcum and the whole of the large bowel showed an intense proliferation of the lymphoid elements but no actual ulceration. A ring of lymphoid tissue similar to that described in the previous cases was found round the ileocæcal valve.

Case 4 (male, aged 6) suffered from diarrhœa of sudden onset which affected the whole family simultaneously. This boy collapsed and died within 12 hours; the rest of the family recovered. Cultures from the stools of a sister yielded *B. dysenteriæ* Sonne.

Post-mortem examination showed the intestines distended with gas; the contents were fluid, with some mucus but no obvious pus or blood. Peyer's patches throughout the ileum were very prominent but showed no signs of necrosis. The lower six inches of the ileum showed intense proliferation of lymphoid elements, increasing towards the caput cæcum where the hyperplasia almost surrounded the bowel. There was considerable reddening and œdema of the large bowel.

Case 5 (male, aged 65 years) had been in poor health for some time; he ate some pork at midday with the rest of his family and was taken ill at midnight with diarrhœa and vomiting, and died within 24 hours. He had no rise of temperature during the illness. The other members of the family escaped without severe symptoms. Post-mortem examination showed the same lymphoid hyperplasia of the ileum and the ileocæcal valve which was noticed in the other cases.

COMMENT

The most striking feature on *post-mortem* examination common to all the cases was the presence of a ring of lymphoid hyperplasia and œdema around the ileocæcal valve; this varied in size and extent from case to case; in some it extended for several inches up the ileum and down the cæcum. In some cases the ring was complete, in others not entirely so, but in every case it was a striking feature. No record of this appearance has been found in descriptions by other workers of post-mortem examinations on cases of dysentery. Charles and Warren[1] give a detailed account of the findings in fatal cases in the Newcastle epidemic but, though they describe folliculitis of the large bowel, which was also noted in the cases recorded above, they do not mention the intense lymphoid hyperplasia at the ileocæcal valve. A possible explanation of this discrepancy is that the ileocæcal hyperplasia may be a feature of all those of the most fulminating cases, of which recorded above were examples.

Cultures were taken from the mucosa and contents of the bowel at several different levels and from the spleen in each case, but no organisms of any pathological importance were isolated. Failure to identify these from any of the cases may be attributable to the fact that in no case was the post-mortem examination made until the second day after death and in some cases not until the third. On account of this failure definite proof exists of the nature of the infecting ganism. The fact that *B. dysenteriæ* Sonne was lated from a sister who had been ill at the same time Case 4 makes it likely that in this case, at any rate, e infecting organism was of the Sonne type.

---

[1] Charles, J. A., and Warren, S. H.: THE LANCET, 1932, ii., 626.

In 1926 Fraser, Kinloch, and Smith [2] reported an tbreak of dysentery in Aberdeen. In 1929 Charles d Warren [1] recorded a similar outbreak in wcastle. Various other writers have described aller epidemics. The attention of this depart nt was directed to the matter by an outbreak in the ldren's ward of the Royal Hospital in 1928, and e then there have been two smaller breaks. In spite of the attention t has been drawn to epidemics of illary dysentery in the last few rs, there does not appear to be eral recognition of the fact that disease is endemic in this country. is well recognised that in certain s of Shiga and Flexner infection toxæmia may be so everwhelming bring about a very early fatal ination. Charles and Warren recorded several cases of the but the Sonne bacillus has in the usually been regarded as only y toxigenic. Fulminating infec with rapid death due to *B. teriæ* Sonne, as in Case 4, does ppear to have been reported That death should occur as esult of a dysenteric infection ut the appearance of the cardinal om of diarrhœa, as in Cases 1 and 2, does eem to have been previously noted. This lity should be borne in mind in cases of death in children.

ost-mortem examinations on all the cases recorded de by Dr. S. C. Dyke, pathologist to the hospital, instance of Mr. J. T. Higgs, coroner for South shire, and of Mr. A. C. Skidmore, coroner to the of Wolverhampton. I am indebted to the coroners d for permission to publish the cases; to Dr. D. E. S. ham, of Upper Gornal, for material; to Dr. M. W. of Wolverhampton, for the history of Case 3; and Dyke for access to his notes and for advice and e.

UBERCULOUS LARYNGITIS:

IMPORTANCE OF EARLY DIAGNOSIS

ROLD BARWELL, M.B. LOND., F.R.C.S. ENG.

G SURGEON FOR DISEASES OF THE THROAT AND EAR, ORGE'S HOSPITAL; LATE LARYNGOLOGIST, MOUNT ERNON HOSPITAL FOR DISEASES OF THE CHEST

RCULOUS laryngitis is pre-eminently a disease early diagnosis is all-important for successful nt. As it is, with exceptions so rare as to be le, a complication of pulmonary tuberculosis, it mally be recognised early if it is looked for; sh here to urge again, as I have done for over that all phthisical patients must have their inspected at regular intervals of a few months, or not they have symptoms referred to the d that they be sent to a laryngologist if this tion cannot be excluded with certainty. A ny consumptives suffer from hoarseness, or aracteristic weak voice; this is often merely t of asthenia, but these patients also have an unusual tendency to attacks of simple laryngitis, partly from the strain of coughing and partly from infection by secondary organisms in the sputum. On the other hand, a tuberculous lesion, perhaps in the posterior commissure or at the upper aperture, does not necessarily cause any symptoms in an early stage, and the disease can, therefore, neither be diagnosed nor excluded by the patient's symptoms alone, but only by laryngoscopy.

FIG. 1

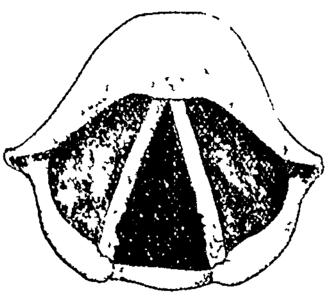

FIG. 5

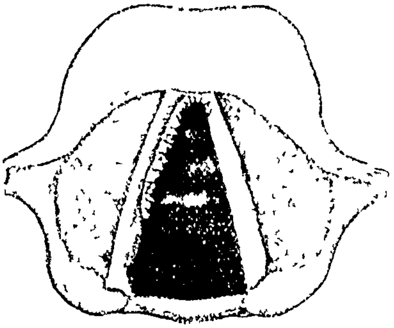

FIG. 1.—Tuberculous infiltration of vocal cords.
FIG. 5.—Epithelioma of vocal cord.

The illustrations are taken from "Diseases of the Larynx," by Harold Barwell, third edition, 1928. Oxford University Press.

Invasion of the larynx is usually the result of the entrance of tubercle bacilli contained in the sputum directly through the epithelium, and takes place most often in the neighbourhood of the vocal process where the mucosa is thin, closely applied to the cartilage, and liable to abrasion from coughing. The earliest lesions are, therefore, most often found at the level of the glottis and tend to spread from behind forwards along the vocal cord, or backwards to the posterior commissure. The upper aperture is seldom involved before the glottis, although not infrequently swelling of the arytenoids is the first lesion to attract attention, and the epiglottis is rarely attacked until the rest of the larynx has been extensively affected. It is often said that pallor is a characteristic feature of tuberculous laryngitis, but this is only partly true. Many consumptive patients are anæmic, and then the larynx, together with the other mucous membranes, will also be anæmic; in other cases the colour is normal or reddened from coughing and irritation by the sputum. Tuberculous granulations are usually pallid, the margins of ulcers are not hyperæmic, and arytenoid infiltrations are pale; but the unaffected portions of the larynx have no characteristic colour, and very often tuberculous infiltration on the cords, ventricular bands, and especially on the epiglottis, has a deeply congested red coloration. Granulations are typically of a soft, gelatinous appearance; when healing occurs there is but little fibrosis or deformity, in contradistinction to the lesions of syphilis or lupus, and stenosis causing dyspnœa is extremely rare.

CLINICAL VARIETIES

As any part of the larynx may be affected, the clinical picture is very variable, but for the sake of clearness five types may be described.

1. In the "chorditic" type the vocal cords are principally affected, and hoarseness and aphonia are early symptoms. The lesions are seldom symmetrical. Swelling and redness confined to one cord is not due to simple laryngitis; it may be caused by traumatism,

syphilis, or early epithelioma, but is highly suspicious of tuberculous laryngitis and should lead to a careful examination of the lungs. The posterior part of the glottis is chiefly affected; a pale shallow ulcer or erosion on the vocal process is very characteristic, or small soft granulations spreading from this region forwards along the cord (Fig. 1). In other cases the *process is more indurative*, and the cord becomes the seat of a firm pink nodular deposit, or again, may be converted into a broad red band of granulation tissue which adheres somewhat to its fellow on abduction. Ulceration is common, and one or both cords may be completely destroyed.

FIG. 2

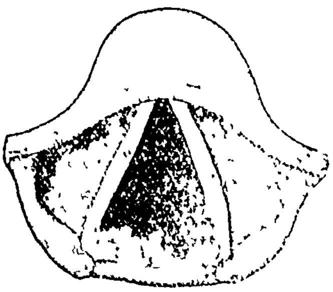

FIG. 6

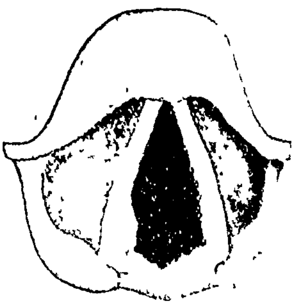

FIG. 2.—Interarytenoid granulations arising from a tuberculous ulcer in the posterior commissure.
FIG. 6.—Pachydermia laryngis.

2. In the "interarytenoid" form the posterior commissure is the region chiefly affected; there may be hoarseness or no symptoms at all, and the disease is usually of a chronic indolent type. The condition may resemble very closely the pachydermatous form of chronic laryngitis and, indeed, pachydermia has been considered by some authorities to be tuberculous. In pachydermia the thickenings are of a firm and solid appearance, of an opaque white or pale pink colour, symmetrically placed with a depression in the middle line of the posterior commissure, while the typically umbilicated swelling of the vocal processes is very characteristic (Fig. 6). On the other hand tuberculous granulations in this situation are irregular and asymmetrical, soft and semi-translucent, and are often but the edge, or the granulating base, of an ulcer seen foreshortened in the mirror (Fig. 2).

FIG. 3

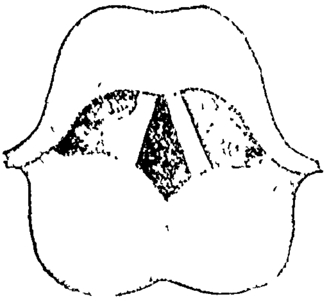

FIG. 7

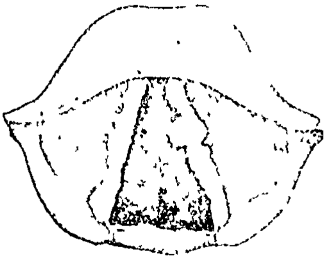

FIG. 3.—Tuberculous infiltration of the arytenoids.
FIG. 7.—Syphilitic infiltration of cords and ventricular bands.

3. In the "aryteno-epiglottic" type the disease, attacking the upper aperture, overshadows the lesions in the interior of the larynx. This form is the most easily recognised, and is the most serious on account of the massive infiltration produced, and because it causes the dysphagia which rapidly undermines the patient's resistance. The pyriform swelling of the arytenoids is distinctive; bilateral, except in the earliest stage, but not always symmetrical, the peculiar pale gelatinous infiltration is highly characteristic and is readily distinguished from the red transparent appearance of true œdema (Fig. 3). On the epiglottis the swelling assumes a sausage-shaped form, is red in colour, and ulceration occurs early on its laryngeal aspect; the swollen epiglottis and arytenoids form a picture which has been likened to a turban and is pathognomonic (Fig. 4).

FIG. 4

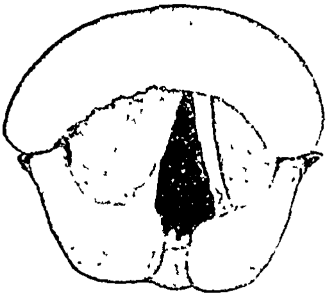

FIG. 8

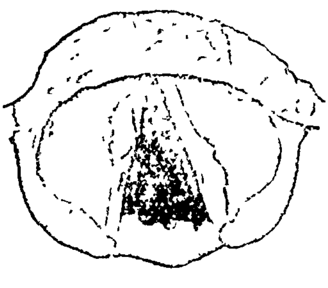

FIG. 4.—Tuberculous infiltration of epiglottis and arytenoids.
FIG. 8.—Syphilitic ulceration of cords and epiglottis.

4. There is a "lupoid" form of tuberculous laryngitis associated with a chronic fibrosing type of pulmonary phthisis; it is characterised by slow progress, little pain, and a tendency to heal with formation of scar tissue. The epiglottis is affected early, and the prognosis is relatively favourable. There is no sharp line dividing this affection from laryngeal lupus.

5 Miliary tuberculosis occurs in the larynx as a terminal affection in rapidly progressing phthisis. The typical miliary tubercles show up as grey points scattered on the bright red swollen mucosa and quickly break down into ulceration. The palate and fauces are often similarly affected, and the lesions are *intensely painful.*

DIFFERENTIAL DIAGNOSIS

The great majority of cases can be readily recognised by inspection, and it is not uncommon for the disease to be diagnosed in the larynx before it has been suspected in the lungs. The difficulty most often encountered by medical officers of sanatoria is to distinguish a simple laryngitis from early tuberculous invasion in a patient known to have phthisis; the error of mistaking catarrhal for tuberculous laryngitis is the less serious, for vocal rest and simple treatment will cure the condition and no harm will have been done. In the earliest stage tuberculous invasion may show little to distinguish it from simple catarrh, and it is therefore wise to treat an apparently simple laryngitis in a consumptive patient with respect and to be guarded in its prognosis. If one cord only be affected, lesion may be due to tubercle, syphilis, cer, or traumatism, but not to catarrh, and ther ulceration nor granulations occur in the latter. distinctions between typical tubercle and typical hilis are very marked. The tuberculous ulcer is w in growth, with ill-defined margin and no rounding injection, and the base is covered by e granulations of a yellowish speckled appearance ; healing contraction, scarring, and deformity are the slightest. In syphilis the superficial ulcer has rell-defined margin surrounded by a distinct zone of peræmia, and its base is smooth and flat ; the deep er is crateriform, with sharply punched-out, dermined, and often "mouse-nibbled" edge ; aling leaves a dense scar tissue with much contraction and deformity. Syphilis shows a predilection the epiglottis and, spreading from the fauces, acks its anterior aspect, whereas tubercle reaches is region from the interior of the larynx, so that eration affects the laryngeal surface and the rest the organ is usually already extensively involved ; philitic lesions, also, often coexist in the uth and pharynx. On the vocal cords the rule especially applicable that tuberculosis attacks e posterior, and syphilis the anterior, regions igs. 7 and 8).

Lupus in the larynx presents strong points of ntrast with the usual forms of tuberculosis. It tends spread from above downwards through the upper r-passages and attacks the epiglottis and upper erture before it reaches the interior of the larynx ; hen the larynx is affected, active or healed lesions e often to be found in the nose, palate, or fauces. differs from tuberculosis also in its painlessness, e nodular character of the infiltration, and the tendency to the production of dense scar tissue causing deformity and stenosis.

From malignant growths the diagnosis is not usually difficult, but a tuberculous infiltration limited to one vocal cord may imitate epithelioma very exactly. This form of tuberculous laryngitis is not very uncommon in elderly men ; the patient comes for examination on account of hoarseness, there is often no suspicion of phthisis, the physical signs may be very indefinite or may appear to be those of a simple chronic bronchitis, and tubercle bacilli may be very scanty or absent. There is no doubt that a number of cases of this form of tuberculosis have been diagnosed and treated as epithelioma. An opaque white appearance of the infiltration is very suggestive of malignancy (Fig. 5), while signs of involvement of the other cord and slight arytenoid or interarytenoid swelling point to tuberculosis. Delayed or sluggish movement of the affected cord is a sign of malignancy, but we must never wait for this sign for, when it is apparent, the disease has extended deeply and the prospect of successful operation is much diminished. These lesions are often too sessile to permit the removal of a portion for biopsy, and this should not be done in any case unless operation has been agreed to, should the examination prove malignancy. These cases constitute some of the most anxious and responsible of laryngological problems. The patient should be given a very complete examination, including skiagraphy of the chest, and, if progress is slow, as it usually is, may safely be watched for several weeks ; but it is better to perform a laryngo-fissure for an infiltration which proves to be tuberculous than to allow an epithelioma to pass beyond the reach of removal by this operation.

CLINICAL AND LABORATORY NOTES

PLACENTA PAPYRACEA AND FŒTUS PAPYRACEUS IN A BINOVULAR TWIN PREGNANCY

By KENNETH MAY, M.B. LOND.
ASSISTANT MEDICAL OFFICER, LAMBETH HOSPITAL, LONDON

ON July 20th, 1931, a patient gave birth to a living ild and to a mummified fœtus at Lambeth Hospital. he was a multiparous woman who had never had ins. Her mother had one twin pregnancy.

Pregnancy was uneventful and labour was normal. The living child was healthy and weighed 6 lb. 10 oz. On examination of the membranes a second placenta was noticed (Fig. 1 A). This was roughly circular, having a diameter of 9 cm. It was flattened and fibrous, and completely separated from the living placenta. Alongside this compressed placenta was a thickened area which gave a sensation of egg-shell crackling, and by radiography the fœtal skeleton was revealed (Fig. 2). When the amnion had been stripped away a fœtus of about 16 weeks' gestation was seen. Its general lie gave the impression that it had been spread-eagled. The skeleton was complete save for one humerus which was found in the membranes. The vault of the skull appeared to have burst open. The following measurements are approximate: diameter of placenta, 9 cm. ; length of spine, 7 cm. ; vertex to rump, 11 cm. ; vertex to heels, 15 cm. ; average width, 4 cm. ; greatest thickness (scapular region) less than 1 cm.

The chief interest of this case lies in its rarity. G. C. Mosher,[1]

FIG. 1

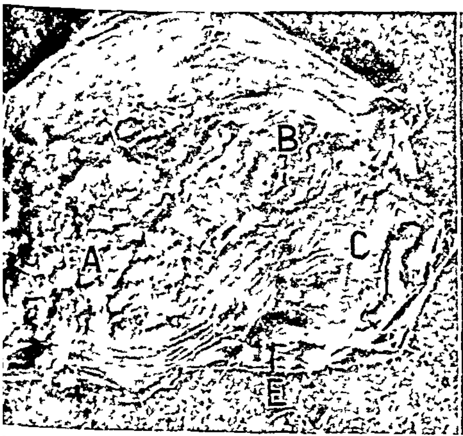

FIG. 2

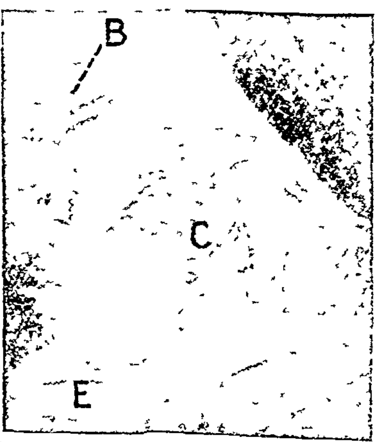

FIG. 1.—Photograph of the membranes, showing the flattened second placenta (A) and the fœtus. (B) is the jaw ; (C) the spine ; and (E) a leg of the fœtal skeleton.
FIG. 2.—Radiogram of the fœtus, for comparison.

---

[1] Amer. Jour. Obst., 1918, lxxviii., 288.

in 1918, was able to collect but 88 cases of fœtus papyraceus associated with a living twin from the literature of the preceding 80 or 90 years. Of interest too is the fact that this was a binovular pregnancy, as a mummified fœtus is said to be commoner with uniovular pregnancies (R. Birnbaum [2]).

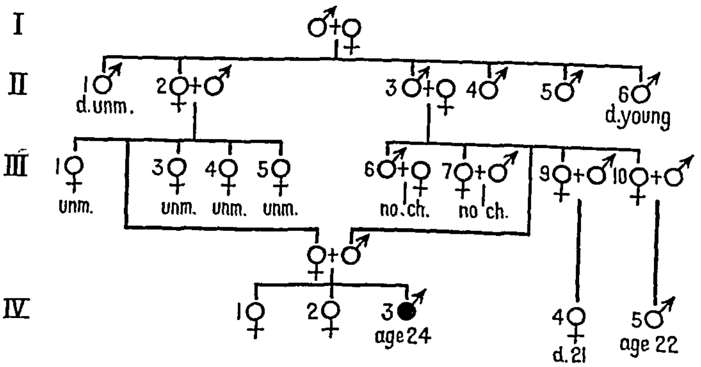
The mechanism of formation is as follows: death of one twin, retention, absorption of fluid, desiccation, compression by the growing twin. The factors influencing one placenta and twin to bring about their death are speculative. The cause of desiccation is also unknown, but its occurrence is presumably essential for retention of the fœtus.

I am indebted to Dr. G. F. Stebbing, who radiographed the specimen, and to Dr. T. McK. Robb, who photographed it and reproduced the radiograph.

A FORM OF BRACHYPHALANGY IN A COUSIN MARRIAGE

BY R. RUGGLES GATES, PH.D., LL.D., F.R.S.
PROFESSOR OF BOTANY IN THE UNIVERSITY OF LONDON

I CHANCED to observe recently a young man who appeared at first to be brachydactylous—i.e., with fingers having two instead of three phalanges, although his parents were normal. As this condition is always inherited as a Mendelian dominant, so far as known, the case was looked into further. The pedigree of this Warwickshire family is given in the accompanying figure.



The parents (III.2 and III.8), who were first cousins, as well as their son and daughter, were seen personally. The series of abnormalities in the son, who was 24 years of age and mentally bright, were quite unknown in any other member of this family through four generations. The second generation consisted of five sons and a daughter, number II.1 dying unmarried, while II.6 died young. The five daughters of II.2 all remained unmarried except III.2, mother of the proponent. From the marriage of II.3 to a normal woman there was a family of two sons and three daughters. The first son and daughter both married but had no children; III.8 was father of the proponent, III.9 had a daughter who died of pneumonia at 21, and III.10 has a son aged 22 years.

The abnormal son was the youngest of three children. IV.1 was apparently normal but died at birth owing to an abnormal presentation. IV.2, a daughter, is perfectly normal, and it now remains to describe the son. He was stout but dwarfed, about 4 ft. 7 in. in height.

Examination of his hands showed that, although his fingers were short and stubby, three phalanges were present in each finger. The basal phalanges were apparently of normal length, but the second and third phalanges were very short. The nails were very small on each finger, or in certain cases quite missing. The thumbs, however, were approximately normal, with large nails. Digit V on each hand was also rather strongly bent (crooked). He was also hexadactylous, a finger of probably full size, judging from the scar, having been removed from the ulnar side of each hand by surgical operation. Unfortunately it was not possible to make any more detailed examination nor to take radiograms. The feet were not examined, but there were stated to be five toes on each foot, with peculiarities similar to those of the fingers.

The inheritance of various kinds of short-finger abnormalities has been described elsewhere,[3] and the considerable recent literature of the subject has been reviewed by MacArthur and McCullough.[4] They describe a pedigree of "apical dystrophy" in which the first and second phalanges were more or less reduced or represented only by the epiphyses, and they point out differences between this condition and brachyphalangy, confining the latter term to those pedigrees in which there is absence or premature ossification of the epiphysis. The present condition resembles brachyphalangy in that the stature as well as the fingers are affected; but, on the other hand, the condition of the nails is like that found in apical dystrophy. Again, in previous pedigrees, the inheritance is that of a simple dominant, with rare cases of skipping a generation only in certain pedigrees, whereas in the present case the most probable interpretation is that the condition is a recessive brought out by cousin marriage.

Hexadactyly is also usually a dominant in inheritance, but in certain recent pedigrees it is clearly a recessive character in the Mendelian sense. The frequent association of two or more abnormalities in the same pedigree is of course well known. In MacArthur and McCullough's pedigree of apical dystrophy it was frequently associated with a variable condition of syndactyly and a well-marked tendency to doubling of the thumbs. The genetic evidence is as yet rarely sufficient to determine whether these conditions and their expression are due to genetically linked genes, the presence of modifying factors, or to single factors environmentally modified in their effects. On general genetic grounds, however, it seems highly probable that such conditions as hexadactyly and shortened phalanges are determined by separate genetic factors.

THE MANCHESTER HOSPITALS.—A poll of the municipal electors was taken at Manchester recently upon an omnibus Bill promoted by the city corporation. Among the proposals defeated were those for requiring the pasteurisation of milk coming into the city, excluding Certified milk and Grade A milk, and for controlling the sale of food by street vendors. The one resolution that was carried was that which provides for the acquisition of land adjoining the Manchester Royal Infirmary which may in future be necessary for the extension of the institution. Even for this there was a majority of only 1180 out of a poll of more than 43,000.—At the recent annual meeting of the Manchester Victoria Memorial Jewish Hospital, Mr. Nathan Laskie, the chairman, claimed that "there was no hospital in the country comparable to it, and that everything known to modern science had been secured." The new theatre is fitted with an apparatus for providing artificial rain on the glass roof in hot weather. The department for paying patients is about to be opened. Cubicles will cost £3 and private rooms £6 per week, inclusive of everything except specialist's fees. "The rooms and meals," it is stated, "will compare with the finest hotels in the land." The extensions have cost £15,000. Last year the hospital spent £567 upon road accident patients, and received £121. Salford Royal Hospital spent £651 in the same way, and received £98.

MEDICAL SOCIETIES

ROYAL SOCIETY OF MEDICINE

SECTIONS OF NEUROLOGY AND PSYCHIATRY

At a joint meeting of these two sections, held on Jan. 19th, the chair was taken by Dr. RISIEN RUSSELL, President of the section of neurology, and a discussion on the mental and physical symptoms of the

Presenile Dementias

was opened by Dr. MACDONALD CRITCHLEY. To the neurologist, he said, the presenile dementias were chiefly a problem of diagnosis. The majority of the deteriorations of late middle life were either syphilitic, arterio-sclerotic, or neoplastic. Smaller groups were the epileptic, the traumatic, and those associated with chronic neurological disorders, such as disseminated sclerosis and encephalitis. There remained a small group which could be separated by exclusion from all these: the true presenile dementias. The chief syndromes were Pick's disease and Alzheimer's disease. Pick had described his two cases in 1892; both had shown a curious psychical defect in life, and at autopsy a peculiar pathological change: symmetrical, localised, bilateral atrophies of the cortex. Only a few score cases had since been recorded. The onset was between the ages of 40 and 60, and females were more often affected than males. A phase of restlessness, agitation, and excitement was followed by dementia associated with focal symptoms, and finally by complete dementia and death. The course was usually slow. The focal manifestations were of all types, one of the commonest being sensory aphasia. Any part of the cortex might show atrophy, but the middle of the temporal lobe was the commonest site. The atrophy was a simple numerical reduction in the total number of cells, particularly in the three upper layers. The remaining cells showed some changes, notably a deposition of iron. The changes were not those of old brains, and did not resemble those of senile dementia. The ætiology was quite unknown. There was nearly always a family history of psychosis.

Alzheimer had described his disease in 1906; it appeared to be a little more common. The symptoms resembled those of Pick's disease, but the course was rather longer. Epilepsy was important. Remissions might occur. The pathological changes were like those of senile dementia, but much more intense and diffuse. "Alzheimer's tangle" appeared in other diseases as well as this. Senile plaques were very common. This condition might be a premature senility or a toxic phenomenon. Probably Alzheimer's and Pick's diseases were less rare than was believed. Diagnosis during life could only be made by exclusion; it was doubtful if the differential diagnosis could be made, except on the family history. Pick's disease had been demonstrated by encephalography, but the method was not to be recommended. The physical signs of the presenile dementias had received little attention, but careful examination would reveal interesting signs in the nervous system. The focal manifestations were extremely varied, as projection, commissural, and association fibres might be implicated. Other signs often present could not be correlated with precise lesions; these were the psychomotor disorders. The two chief types were the hypokinetic (immobility resembling Parkinsonism, slowness, resistance amounting to hypotonus and katatonia) and the hyperkinetic (restlessness and agitation, bizarre repetitive movements, grasping movements, and conveying everything to the mouth).

Dr. R. D. GILLESPIE offered a similar classification into (1) simple presenile dementias, (2) Alzheimer's disease, (3) Pick's disease, (4) presbyophrenia, and (5) the other conditions described by Kraepelin. He said that the subject had received inadequate attention. The histopathological changes found were too variable to form a basis for classification. The psychiatrist saw little of Alzheimer's and Pick's diseases outside institutions because the patients went to the neurologist as suspected intracranial tumour. A progressive failure of intellect and interest was the fundamental symptom of the simple group, and on this secondary intellectual, affective and conduct disorders might be superimposed. Symptoms on the symbolic level were important in differentiation. In the first group the intellectual symptoms persisted alone for some years. This group might be merely the early stage of one or other of the subsequent groups. On the whole, however, Dr. Gillespie thought there was a real group of this kind, as he had known the symptoms last for four or five years without any focal manifestations. The onset was so insidious that recognition was difficult at first. Slight deterioration and behaviour changes might set in as early as the late 'thirties. Little was known of the ætiology of any of the conditions; and there were no specific histopathological changes. Alzheimer's fibrillary changes, senile plaques, and Simchowic's granulo-vascular degeneration might be found in any group. There seemed to be a racial incidence.

Presbyophrenia was a confused concept, the term being differently used by different authors. According to one author, the leading symptom was a memory defect with confabulation, but for Bleuler the condition was equivalent to Alzheimer's disease. Kraepelin placed it among the senile dementias, and doubted whether it was a separate entity. The term could conveniently be retained for patients with retention defect and confabulation, but continued intellectual ability.

Dr. T. R. HILL selected only those dementias characteristic of the age-period 40-60, excluding late dementia præcox, gross organic disease, general paralysis, and toxic cases. There remained a number of types of dementia, chiefly falling into two groups: those associated with neurone degeneration, and those following cerebral vascular changes. These two might be compared with parenchymatous and interstitial syphilis. The first group included Alzheimer's and Pick's diseases, presbyophrenia, and early senile dementia. It was doubtful if there was any clearly defined condition to which the term "presbyophrenia" could be applied, unless it were to some anomalous cases of senile dementia. Alzheimer's disease had been described between the ages of 30 and 40, and once in childhood. Its average duration was four and a half years, but cases had been known to last 20 years. The definite familial incidence noted in Pick's disease had not been seen in Alzheimer's. Despite the uniform clinical picture, there was considerable individual variation. Aphasia, apraxia, and visual agnosia were less prominent and early than in Pick's disease. An incessant busyness seemed to fill the clinical picture at one stage. Positive symptoms were most marked, whereas in Pick's disease the negative symptoms were outstanding: inertness, lack of interest, and complacency. The course in Pick's disease was usually two to three years, though some cases had lasted 15 years. The one rule that seemed to regulate the focal atrophies was that the pre- and post-central and visuo-sensory areas should always be spared. Certain groups of cells seemed predestined to pathological change.

Arterio-sclerotic dementia was much commoner and more chronic. Focal symptoms were multiple, the aphasia being of sudden onset and sometimes transient. Insight was well preserved. The Pick's or Alzheimer's disease was brought to the doctor; the cerebro-arterio-sclerotic came himself, gave a clear account of his disease, and was anxious. Moreover, the nucleus of the personality was well preserved, but in Pick's or Alzheimer's disease it was profoundly shaken.

DISCUSSION

Dr. H. H. Devine said that restlessness in these cases might be due to bewilderment as a result of not being understood. When they were given a good environment their restlessness disappeared. It was a matter of very interesting speculation how much mind these patients had and to what extent they appreciated the environment, but were unable to express themselves.

Sir Robert Armstrong-Jones spoke of the social and family aspect of the problem. Cases of this kind were often not certified, but their affairs were placed in the hands of a receiver. The ordinary senile deterioration might be said to become pathological if there was marked loss of memory, marked change in personal habits or conduct, purposeless restlessness, or extreme fatuity and lethargy, or if there was a growing antipathy towards those formerly near and dear. The changes depended on the inherent durability of the neurone. It was doubtful if any form of insanity proper especially characterised senility, but the dementia of old age was quite characteristic. There was a slurred activity of thought, a diminished receptivity, and marked confusion, especially about relations. Old people often suspected those about them of plotting to rob them, and undesirable but plausible people were trusted instead of old friends. Here the protection of the Master in Lunacy was of inestimable value to the family. These people should not be allowed to make wills without the consent of the Master. Some of the symptoms related to the sexual instincts, the moral faculties being the first to go, and the cases might come before the courts. The commonest associated symptom was urinary trouble, often ending in fatal cystitis or pyelitis.

Dr. G. W. B. James related some case-histories of Alzheimer's disease. One woman had died after three and a half years. Three brothers had already died of the disorder, and the father had almost certainly had Pick's disease. The mother had died of cerebral hæmorrhage. An increasing number of patients in the presenium was seen with anxiety, inability to concentrate, fear of new situations, and an apparent dementia. These people had not previously suffered from anxiety.

Dr. R. M. Stewart said that the most striking feature of Pick's disease was the gross naked-eye change, and yet microscopically the change was limited to the supragranular cortex. Similar histological changes in aments did not produce such a gross modification. Atrophy of the corpus callosum might play a part in producing the physical signs.

Dr. Letitia Fairfield remarked on the rise of the suicide rate in both sexes between 45 and 55. This gave a serious aspect to mental symptoms at this age. She would like to know the connexion between the mental symptoms and the endocrine changes of the period. Clinically it was important to know how much to attribute to mental changes, and how much to temporary disturbances that would right themselves.

Dr. Critchley, in reply, said that the familial incidence of Alzheimer's disease had not been recognised. Alleged cases in young persons were probably something else. The more demented an old person was the more likely were senile plaques to be found, but their significance was still far from clear. The absence of radial or even retinal arterio-sclerosis did not exclude cerebral arterio-sclerosis, and this was by far the commonest cause of presenile dementia. Remissions and emotivity indicated arterio-sclerotic dementia. He had seen a case of Pick's disease with extreme precentral atrophy.

Dr. Gillespie, also in reply, agreed with Sir Robert Armstrong-Jones that the importance of diagnosis lay on the legal side.

Dr. Hill regarded the restlessness of Pick's disease as a loss of inhibition, the pathological process being less intense than in Alzheimer's disease. Any case which from the start had no insight was probably not arterio-sclerotic.

SECTION OF PHYSICAL MEDICINE

At a meeting of this section on Jan. 20th, with Sir Robert Stanton Woods, the President, in the chair, a discussion took place on

Physical Methods in the Treatment of Heart Disease

Dr. F. G. Thomson (Bath) said that although during the last ten years more attention had been paid to physical medicine, comparatively little had been given to its application to heart disease; indeed, physical methods seemed to have been in use more 25 years ago—chiefly in the form of effervescing baths, resistance exercises, and the like, as carried out at Nauheim. The vogue of Nauheim received a check from some devastating criticisms by the late Sir James Mackenzie. The speaker felt, however, that much more should be done by physical means for heart disease which in this country accounted for more deaths than any other disorder. With one or two exceptions, drugs had only a limited value in these disorders. Rest, duly regulated exercise, changes of environment, and, as far as possible, freedom from anxiety were all very important.

To estimate the true value of any therapeutic procedure, it was first necessary to consider its physiological effects on the normal person. Though the effect of baths on the heart was indirect it was very real, since the cutaneous and subcutaneous vessels contained at any one time a large proportion of the total body content of blood, and this superficial blood stream was readily influenced. With certain forms of bath the main effect was an active capillary dilatation, and an increased blood flow, with a desirable readjustment of pressure. The reflex result of this on the heart was to slow the beat and increase its propulsive force. If this bathing was combined with the drinking of appropriate waters the benefit might be increased. One effect was to reduce obesity, and hasten oxidation and elimination of waste products. Should any arterial spasm be present, this was much relieved or overcome by the baths. Similarly, the tone and quality of the heart muscle was increased. Electrotherapy seemed to be of but limited applicability to cardiac cases; indeed, the only form of electrical treatment which he had und to be of real value was that originally advocated y Sir Clifford Allbutt, the high-frequency current, hich that authority advocated for abnormally high lood pressure.

It was necessary to exclude from this treatment all ases of malignant endocarditis, however chronic or pparently latent; also all cases of recent rheumatic arditis. Old rheumatic heart affection which had become stabilised with time and in which there was a non-progressive mitral lesion was not necessarily precluded as unsuitable for physical methods f the myocardial state suggested the desirability of treatment on those lines: but he would not so treat cases having advanced myocardial disease, especially if there was concomitant renal disease. Indeed, in a general way, any case with a rheumatic history or having an obvious rheumatic lesion should be viewed with suspicion from the point of view of physical treatment. One must also rule out cases of advanced arterio-sclerosis, especially if the patient's condition suggested that there might be any vascular cerebral lesion. Another reason for exclusion was tachycardia when associated with hyperthyroidism.

Among conditions suitable for physical methods were, firstly, cases which were recovering from a toxic myocarditis which had followed on such an illness as influenza or tonsillitis, this toxin having definitely debilitated the heart muscle. He thought that the importance of infection in causing cardiac disability was not always sufficiently recognised. Another class of suitable case was the so-called D.A.H. (disordered action of the heart), the case of tachycardia which showed an exaggerated reaction to exertion, the case which showed the "effort syndrome." Next he mentioned functional conditions, as when extrasystoles were noted, and also dyspnœa due to gastro-intestinal disorders. The commonest of these latter were constipation and dyspepsia, possibly associated with chronic appendicitis or cholecystitis. Most of these patients showed, also, a heightened sensitivity, bordering on neurosis. Cases of myocardial debility and obesity were suitable for treatment by physical methods. And early cases of myocardial degeneration, which often were associated with hyperpiesis and symptoms suggestive of coronary insufficiency, were also very suitable.

A class of case in which spa and physical treatment was especially valuable was that showing chronic myocardial degeneration in an early stage. He instanced the case of the average middle-aged man who began to get somewhat breathless on exertion and said he felt a tightness across his chest when walking briskly uphill. He probably still ate heartily, and took less exercise than he should, and the veins on his face became prominent. The heart might be somewhat enlarged, and the aortic sound had an ominous ring, with a raised blood pressure. If untreated, such a man would go on to develop an irremediable form of myocardial degeneration. Almost certainly his metabolism was defective. Then oncoming obesity imposed a further serious handicap. Obesity was always a disability at this stage of life; it was said that in the obese the mortality from heart disease was two and a half times that among ordinary non-obese people. Once the coronary vessels and the myocardium had become the seat of advanced degeneration, no form of treatment could be of real benefit. This fact emphasised the lesson that treatment should be instituted as early as possible.

DISCUSSION

Dr. B. T. **Parsons-Smith** said it was usual to divide heart affections into two main groups—functional and structural or organic. In both kinds there was defective circulatory reserve; the circulatory mechanism of the heart suffered embarrassment, so that the train of symptoms known as the effort syndrome resulted. He considered that general massage and graduated exercises were very important in cases of heart affection. These increased the strength of the myocardium and improved the mechanism of the general circulation. Both, however, must be administered with great caution, and after careful examination of the patient. Whenever possible, results should be checked by tests of exercise tolerance. Great benefit sometimes followed deep breathing at the rate of seven or eight breaths per minute, for ten minutes at a time. Following this, he had noted a definite increase in the "R" wave on the electrocardiogram. Certainly deep breathing exercises had an improving influence on the mechanics of the circulation, as the auricular efficiency was enhanced, and in mitral stenosis the auricular waves were increased in voltage by this means.

Dr. T. F. **Cotton** referred to the discordant views held as to the effect of digitalis in cases of heart failure with a normal rhythm, and the important place which physical treatment held in cardiovascular conditions, deaths from which, recent statistics showed, were on the increase. Of all diseases of the circulatory system the most common was hypertensive heart disease, including arterio-sclerosis. It was important to consider particularly the cutaneous blood-vessels and their response to mechanical, thermal, and electrical stimuli. The essential vascular defect was usually structural, and a contributory cause was arterial spasm, and, often, a vasoconstriction from vasomotor influences. Following the action of the stimuli mentioned it seemed clear that a release of diffusible vasodilator substance took place. Even with intense diathermy the degree of heat penetration was but slight, and experience showed that electricity was not effective in controlling anginal pain. If it was sought to record the end-results of physiotherapeutic treatment in terms of blood pressure, not many therapeutic triumphs would be handed down. The relief of symptoms was not always dependent on the control of pathological processes.

Dr. **Geoffrey Holmes** (Harrogate) said his experience had been mainly in the treatment of heart disease by balneological methods. In some other diseases the heart condition was such that considerable judgment was required in modifying the bath treatment to suit it. In association with rheumatic conditions the vascular states fell into two groups: (1) valvular disease; (2) myocardial weakness and anæmia associated with the chronic infective types of arthritis. Sometimes one of these supervened on the other. The heart condition of a patient might be so poor that the bath treatment appropriate to his joints was impossible because of the state of his heart. In bath treatment much had to be left to the actual technician, and knowledge as to the amount of bath to give for certain states was only gradually being acquired. Following a short bath of a temperature of 99° to 104° F. there was an immediate rise in the systolic pressure, but, almost always, an increasing drop in the diastolic pressure. Even in the case of the normal person, indulging in a hot bath produced profound changes in the heart's action. The principal kinds he used were immersion baths, massage baths, packs, and poultices. Carbon dioxide baths definitely affected the basal metabolism, caused an increased flow of blood through the peripheral vessels and so relieved the heart. For some time he had been using sulphur baths aerated with CO_2. He considered the most important test of results to be the exercise tolerance; if this was improving there was little need to trouble about the blood pressure readings. He also was a believer in mustard liver packs for auricular fibrillation. These physical methods did not interfere with digitalis and other drug treatment of the patient, and a combination of the administration of vasodilators and physical methods was better than using either separately.

Dr. W. P. **Kennedy** said that deep inspiration prolonged diastole and increased the tone of the cardiac muscle, and a sequel of this was to stimulate the pulmonary venous flow, and to dilate the infundibular vessels.

Dr. R. **Timberg** said that in Sweden 50 years ago physiotherapeutic measures were largely practised. At about that date, Swedish people lived more well than wisely, and their comparative lack of exercise brought about a great prevalence of obesity. Physical methods beneficially influenced the systemic, particularly the pulmonary and the portal circulation. It was possible to regulate the heart to a great extent by stimulating the vagus. In his practice he attached great importance to deep breathing.

SECTIONS OF RADIOLOGY AND OBSTETRICS

A joint meeting of these sections on Jan 20th, with Dr. **Russell Reynolds**, President of the section of radiology, in the chair, was devoted to a discussion on the

Radiotherapy of Non-malignant Gynæcological Conditions

Dr. N. S. **Finzi** said that irradiation treatment of menopausal menorrhagia in patients over 38 was so certain that surgery was unjustifiable, in view of its increased risk and the long convalescence required. X rays and radium were equally effective; X rays were easier for the patient, especially if spread over three months, as in his own technique, but the result with radium was quicker. Examination under anæsthesia and diagnostic curettage were often advisable. The dose of radium used was 50 mg. in a 2·0 mm. platinum filter for 48 hours. In treating patients under 38 for menorrhagia there was a danger of menstruation returning, and if pregnancy occurred the fœtus might be deformed, microcephaly being the commonest abnormality. Small doses of X rays might be used for restoring normal menstruation in young patients. X rays could be used in uncomplicated cases of fibroids, with patients over 38, even when the uterus was very large; he had successfully treated one case in which the uterus was up to the ensiform cartilage. Younger patients with severe heart disease or anæmia were also suitable subjects if surgery was contra-indicated. Radium might be used in similar cases, especially when examination under anæsthesia was advisable. Surgery was indicated where the patient was under 38, where the fibroids were degenerate or calcified, subperitoneal pedunculated, completely or partially polypoid, or purulent or gangrenous, or where there were pyosalpinx or old tubo-ovarian inflammation, malignant degeneration, or severe compression symptoms. For endometrioma full doses were necessary; deep X ray treatment should be given as for carcinoma. Cases of pelvic inflammation responded to very small doses of penetrating X rays.

Mr. **Malcolm Donaldson** said that in uterine hæmorrhage examination under anæsthesia was essential, except in cases of pure menorrhagia, which might be treated by X rays. He emphasised the necessity of educating the public to appreciate the importance of an exact diagnosis made by curettage in cases of excessive or irregular menopausal hæmorrhage. In favour of X rays was the absence of an anæsthetic and lying-up. Under anæsthesia carcinoma and inflammatory conditions could be excluded, and radium was then preferable. In addition, application of radium to the cervix might be found to diminish the incidence of carcinoma. This was supported by experiments on the production of tar cancer in normal and irradiated animals. Fibroids might be treated by radium or X rays if the uterus was not much larger than a fœtal head, subject to the contra-indications mentioned already. Some fibroids remained the same size and some diminished, the result probably depending on the amount of muscle present. The effect of irradiation was definitely on both ovary and uterus. *Small doses of radiations* were beneficial in tuberculosis of the cervix or vagina. In women under 40 the treatment of irregular hæmorrhage and menorrhagia by radiological methods was very rarely advisable.

Dr. F. **Hernaman-Johnson** said that X rays probably also prevented carcinoma. Radium was more liable to cause vomiting and upset the patient. Women were more likely to come for treatment if they know it can be given without an anæsthetic. X rays very seldom failed in women over 40. Menopausal symptoms were not worse than at the normal menopause, and sex-life appeared to be unaltered.

Mr. **Norman White** gave the results of 323 cases treated with radium at University College Hospital. The most satisfactory dose to produce amenorrhœa, he said, was 50 mg. for 60 hours, with screenage equivalent to 1·5 mm. platinum. Patients under 35 were rarely suitable for radium treatment; there was only a 50 per cent. chance of decreasing the loss at the periods, short of causing permanent amenorrhœa. The menopause in young patients was liable to be associated with severe neurasthenia, and three cases of mild Graves's disease had occurred among eleven cases of radium menopause under the age of 35 Radium treatment seemed to be without risk when used in suitable cases. No case of carcinoma of the uterus had been found after radium treatment in this series.

Miss B. E. **Turner** quoted statistics of 55 cases treated at the Royal Free Hospital.

Dame **Louise McIlroy** said that curettage and microscopical examination of curettings were essential when radiological treatment was undertaken for uterine [illegible] logists should try to find a [illegible] menstrual loss without producing amenorrhœa.

Dr. **Elizabeth Hurdon** said that 96 per cent. of cases of menorrhagia were cured by small doses of radium and she did not think large doses should be given as a routine; the treatment could be repeated in the few cases of failure.

The **Chairman** emphasised the necessity of stating what screen was used in radium treatment. He drew attention to the fact that after treatment the patient commonly had an excessive period, and there was no indication that the treatment had failed.

MEDICAL SOCIETY OF LONDON.

Anæsthesia During Labour

At a meeting of this society on Jan. 23rd, Sir John Broadbent, the President, was in the chair, and a discussion took place on anæsthesia during labour.

THE GYNÆCOLOGIST'S POINT OF VIEW

Mr. Leslie H. W. Williams said that labour was painful for many hours, particularly so at two periods: (1) when the first stage was just completed and the head was beginning to distend the vagina; (2) at the time of delivery through the vulva. For the relief of pain, therefore, something was needed which would act over a long period and could be reinforced at will. The ideal means of relieving the pain of labour still remained to be discovered. Admittedly gas-and-oxygen was the best anæsthetic for the last two or three hours of childbirth, but efforts were still being made to find a drug more powerful than chloral and bromide for the first stage. Some patients became wildly excited, even maniacal, under some of the vaunted new drugs, and exhibited other signs of poisoning, while others seemed to have little relief from pain. In recent years gas-and-oxygen had been widely advocated, especially by anæsthetists, but they were considering only the second stage, since this anæsthetic could not serve throughout labour.

The method practised by *Gwathmey*, of which Mr. Williams's own experience was very slight, seemed to have great possibilities.

As soon as the patient began to show real distress, gr. 1/6 of morphia dissolved in 2 c.cm. of a 50 per cent. magnesium sulphate solution was given intramuscularly, and during the first stage two further injections of the mag. sulph. solution were given alone; this deepened and prolonged the action of the morphia. Just before the descent of the head into the pelvic brim, rectal injection of a mixture consisting of ether and olive oil, with a small amount of quinine and alcohol, was given. Sometimes a smaller dose of this mixture could be given later.

The method seemed to merit a much more extensive trial in this country.

Twilight sleep deserved a wider use. Its employment was fairly usual in maternity hospitals for inert uterus or excessive first-stage pains with but little dilatation of the cervix. All Mr. Williams's private cases were given some modification of twilight sleep. The following was a modified scheme of administration of scopolamine and morphia which had undoubted value.

At the first sign of distress the mother was given gr. ¼ of morphia and gr. 1/100 of scopolamine, and she subsequently received gr. 1/200 scopolamine at two-hourly intervals for two days, and later gr. 1/300 at three-hourly intervals if required. This treatment could be maintained until the actual expulsion of the child, but his own practice was to stop the scopolamine at the beginning of the second stage and continue with intermittent chloroform, gas-and-oxygen being, however, even better.

It was important, in every case so treated, to ensure that the woman was not left alone; the obstetrician should be present, if possible, the whole time, and a nurse must always be at hand to relieve thirst. Occasionally patients so treated became hysterical, even maniacal, and when that occurred the scopolamine must be stopped. A further disadvantage was that some of the children born under this régime were in some degree asphyxiated. This asphyxiation, however, did not last long if careful provision of an airway was made.

The use of the *barbiturate* preparations by the intravenous route he considered inapplicable in obstetrics, since, apart from their well-known dangers, the duration of their analgesia was not sufficient. Nor did he like drugs, like avertin, per rectum, not only because their retention was difficult, but because their use militated against a clean confinement. Barbiturates given by the mouth showed an extraordinary variability of effect. Nembutal was now put up in grs. 1½ capsules, sodium amytal in grs. 3 capsules. He had frequently given 7 or 8 capsules in the course of a labour. The maximum safe dose, however, was considered to be 4 capsules. Another method was to give nembutal and chloral hydrate, but he had not observed advantage from this in his practice. However well nembutal may have acted in the early stages of labour, some other anæsthetic needed to be added for the second stage.

For this second stage *gas-and-oxygen* was far and away the best, as it had no adverse effect on the uterine contractions, and the baby was never affected. Second in value at this stage he placed *chloroform* when the foregoing was not available, and often it was not because of the cumbersome apparatus necessary for its administration. By means of a Junker apparatus the nurse could keep the patient in a state in which she was unconscious of any suffering. Chloroform could also be administered on an open mask or by means of 20 minim capsules (Brisettes), which were crushed and slipped inside the lint covering the ordinary anæsthetic mask. Six to ten of these capsules were used in the course of an hour. In operations for the actual extraction of the child the anæsthesia should be allowed to diminish to as light a degree as possible, so as to permit of the resumption of the uterine contractions.

THE ANÆSTHETIST'S POINT OF VIEW

Dr. Douglas Belfrage said that he would speak only of those methods of which he had had personal experience. For the second, expulsive, period of labour the choice must be made from the anæsthetic drugs in general use: ether, chloroform, and gas-and-oxygen. The latter was the only one which fully answered the requirement of abolishing pain without interfering with the uterus or injuring the child. The other two—especially chloroform—inhibited the uterine muscle when used in sufficient concentration adequately to relieve pain. The objection to gas-and-oxygen anæsthesia was the cumbersome apparatus; efforts were now being made to greatly lessen this disadvantage, and apparatus weighing not more than 50 lb. had been constructed.

It was more difficult to secure to the woman a first stage free from pain. Theoretically this could be done either by making sure she felt no pain, or by ensuring that she remembered nothing of it afterwards. He considered that in this stage morphine, omnopon, and scopolamine had stood the test, also the barbitones and avertin. Morphine-scopolamine and omnopon-scopolamine he believed had now settled into their place in the anæsthesia of labour. The dangers and disadvantages of prolonged twilight sleep were now well recognised. Of pernocton he had had an unfortunate experience because of the amount of restraint the patients required, though their complete obliviousness of what had transpired was unquestionable. Nembutal he regarded as a perfectly safe drug when rightly handled. When used alone, even when morphia had been given beforehand, there was considerable restlessness and struggling, but if O'Sullivan and Craner's technique was followed this tendency was almost absent. The first dose consisted of grs. 3 of nembutal, followed ten minutes later by grs. 30

heart's action. The principal kinds he used were immersion baths, massage baths, packs, and poultices. Carbon dioxide baths definitely affected the basal metabolism, caused an increased flow of blood through the peripheral vessels and so relieved the heart. For some time he had been using sulphur baths aerated with CO_2. He considered the most important test of results to be the exercise tolerance; if this was improving there was little need to trouble about the blood pressure readings. He also was a believer in mustard liver packs for auricular fibrillation. These physical methods did not interfere with digitalis and other drug treatment of the patient, and a combination of the administration of vasodilators and physical methods was better than using either separately.

Dr. W. P. **Kennedy** said that deep inspiration prolonged diastole and increased the tone of the cardiac muscle, and a sequel of this was to stimulate the pulmonary venous flow, and to dilate the infundibular vessels.

Dr. R. **Timberg** said that in Sweden 50 years ago physiotherapeutic measures were largely practised. At about that date, Swedish people lived more well than wisely, and their comparative lack of exercise brought about a great prevalence of obesity. Physical methods beneficially influenced the systemic, particularly the pulmonary and the portal circulation. It was possible to regulate the heart to a great extent by stimulating the vagus. In his practice he attached great importance to deep breathing.

SECTIONS OF RADIOLOGY AND OBSTETRICS

A joint meeting of these sections on Jan 20th, with Dr. **Russell Reynolds**, President of the section of radiology, in the chair, was devoted to a discussion on the

Radiotherapy of Non-malignant Gynæcological Conditions

Dr. N. S. **Finzi** said that irradiation treatment of menopausal menorrhagia in patients over 38 was so *certain that surgery was unjustifiable, in* view of its increased risk and the long convalescence required. X rays and radium were equally effective; X rays were easier for the patient, especially if spread over three months, as in his own technique, but the result with radium was quicker. *Examination under anæsthesia and diagnostic curettage* were often advisable. The dose of radium used was 50 mg. in a 2·0 mm. platinum filter for 48 hours. In treating patients under 38 for menorrhagia there was a danger of menstruation returning, and if pregnancy occurred the fœtus might be deformed, microcephaly *being the commonest abnormality.* Small doses of X rays might be used for restoring normal menstruation in young patients. X rays could be used in uncomplicated cases of fibroids, with patients over 38, even when the uterus was very large; he had successfully treated one case *in which the uterus was up to the ensiform cartilage.* Younger patients with severe heart disease or anæmia were also suitable subjects if surgery was contra-indicated. Radium might be used in similar cases, especially when examination under anæsthesia was advisable. Surgery was indicated where the patient was under 38, where *the* fibroids were *degenerate* or calcified, subperitoneal pedunculated, completely or partially polypoid, or purulent or gangrenous, or where there were pyosalpinx or old tubo-ovarian inflammation, malignant degeneration, or severe compression symptoms. For endometrioma full doses were necessary; deep X ray treatment should be given as for carcinoma. Cases of pelvic inflammation responded to very small doses of penetrating X rays.

Mr. **Malcolm Donaldson** said that in uterine hæmorrhage examination under anæsthesia was essential, except in cases of pure menorrhagia, which might be treated by X rays. He emphasised the necessity of educating the public to appreciate the importance of an exact diagnosis made by curettage in cases of excessive or irregular menopausal hæmorrhage. In favour of X rays was the absence of an anæsthetic and lying-up. Under anæsthesia carcinoma and inflammatory conditions could be excluded, *and radium was then preferable. In addition,* application of radium to the cervix might be found to diminish the incidence of carcinoma. This was supported by experiments on the production of tar cancer in normal and irradiated animals. Fibroids might be treated by radium or X rays if the uterus was not much larger than a fœtal head, subject to the contra-indications mentioned already. Some fibroids remained the same size and some diminished, the result probably depending on the amount of muscle present. The effect of irradiation was definitely on both ovary and uterus. Small doses of radiations were beneficial in tuberculosis of the cervix or vagina. In women under 40 the treatment of irregular hæmorrhage and menorrhagia by radiological methods was very rarely advisable.

Dr. F. **Hernaman-Johnson** said that X rays probably also prevented carcinoma. Radium was more liable to cause vomiting and upset the patient. Women were more likely to come for treatment if they know it can be given without an anæsthetic. X rays very seldom failed in women over 40. Menopausal symptoms were not worse than at the normal menopause. and sex-life appeared to be unaltered.

Mr. **Norman White** gave the results of 323 cases treated with radium at University College Hospital. The most satisfactory dose to produce amenorrhœa, he said, was 50 mg. for 60 hours, with screenage equivalent to 1·5 mm. platinum. Patients under 35 were rarely suitable for radium treatment; there was only a 50 per cent. chance of decreasing the loss at the periods, short of causing permanent amenorrhœa. The menopause in young patients was liable to be associated with severe neurasthenia, and three cases of mild Graves's disease had occurred among eleven cases of radium menopause under the age of 35 Radium treatment seemed to be without risk when used in suitable cases. No case of carcinoma of the uterus had been found after radium treatment in this series.

Miss B. E. **Turner** quoted statistics of 55 cases treated at the Royal Free Hospital.

Dame **Louise McIlroy** said that curettage and microscopical examination of curettings were essential when radiological treatment was undertaken for uterine hæmorrhage. Radiologists should try to find a method of diminishing menstrual loss without producing amenorrhœa.

Dr. **Elizabeth Hurdon** said that 96 per cent. of cases of menorrhagia were cured by small doses of radium and she did not think large doses should be given as a routine; the treatment could be repeated in the few cases of failure.

The **Chairman** emphasised the necessity of stating what screen was used in radium treatment. He drew attention to the fact that after treatment the patient commonly had an excessive period, and this was no indication that the treatment had failed.

Mr. J. P. **Hedley** agreed that, within limits, the less drugs the woman in labour was given the better. Paraldehyde was a safe drug to use. He was in accord with all that had been said concerning chloroform.

Dr. B. **Schlesinger** asked what method of anæsthesia in labour left the infant at its best; was not nembutal liable to leave the child cyanosed ? Was chloroform safe for the infant ?

Mr. D. M. **Roy** said that if one restrained a patient to whom nembutal had been given it was evident that the whole musculature was working. He assumed that when so much muscular energy was being expended there could not be the needed concentration on the expulsion of the child. It seemed a pity to use any method of inducing analgesia which minimised or did away with the coöperation of the woman; it should be possible to dull her pain without destroying her consciousness. Admittedly some women wished to be oblivious of the whole proceeding, but others preferred to know what was going forward.

Dr. **Jenner Hoskin** asked whether any modification of anæsthesia had been devised to suit mothers with damaged hearts who were passing through labour—i.e., mitral stenosis without definite failure.

Mr. W. **McKim McCullagh** said he was attached to a hospital at which 1600 deliveries were effected per annum, and all the various anæsthetics had been tried there. In the last five years the only death from anæsthesia was in a patient who was given chloroform, death resulting from atrophy of the liver. Morphia and magnesium sulphate has been tried, and no effect was traced to the magnesium sulphate.

Mr. W. **Gilliatt** did not think it would be denied that all anæsthetics delayed the uterine contractions. It was not wise to lead every mother to believe she would pass through a painless labour; rather she should be told it would be accompanied by pain, but that efforts would be made to lessen it. Then it would not be necessary to drug her throughout the labour. He had had no ill-effects from nembutal and chloral; there was an absence of excitement in the mother and of disquieting symptoms in the baby.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE

Bacteriophage

Dr. G. **Carmichael Low**, the President, took the chair at a meeting of this society held at Manson House on Jan. 19th, when Dr. F. M. **Burnet** read a paper on recent work on the Biological Nature of Bacteriophages.

He said that the active agent was particulate and varied considerably in size—between 10 and 60 μ—though the particles of a given phage were nearly always uniform in size, and the size was independent of the organism on which the phage was grown. The rate of inactivation by heat changed with the temperature in a fashion characteristic of the heat denaturation of proteins. The influence on heat inactivation of solutions containing different proportions of bivalent and monovalent kations indicated that the surface condition of phage was similar to that of bacteria and other living organisms, and that phages, even when purified by the elimination of bacterial antigens, were capable of inducing the formation of specific antibodies. All the evidence was therefore compatible with the view that the phage particles were definitely organised bodies reproducing themselves true to type, and largely composed of protein. Some of the large-particle phages strikingly resembled minute bacteria in their behaviour. True agglutination of washed phage particles could take place; non-multiplying bacteria could be coated with phage and then agglutinated specifically with antiphage serum, and in the course of phage multiplication a specific soluble substance was produced which was separable from the phage particles by ultra-filtration, and could also react with the specific antibody of the phage serum. The problems of lysogenicity had great theoretical interest. Certain quite characteristic bacterial strains could, by certain manipulations, be used to induce typical lysis either of the homologous strain or of another. Apparently normal strains of coliform bacteria had regularly produced a phage lysing Shiga-dysentery cultures. Lysogenicity had been found surprisingly common in salmonella cultures, and a large number of phage types could be obtained from cultures of a single species. Lysogenicity was not an essential characteristic of the species. The relationship demonstrated could only exist between two sets of biological entities when their evolution and differentiation had been essentially independent. In other words, the phenomena of lysogenicity indicated that bacteriophage formed a group of independently evolved living organisms capable of entering into parasitic or symbiotic relationships with bacteria. Dr. Burnet concluded, therefore, that bacteriophages were independent micro-organisms, viruses which were obligate parasites or symbionts of bacteria. He suggested a classification according to particle or plaque size, serological character, and resistance type.

Colonel F. P. **Mackie** showed slides illustrating the methods in use in Bihar and Orissa and in Assam for the isolation and standardisation of bacteriophages, and for the detection and typing of natural and unknown phages by testing them against a series of phage cultures of different specific resistance. A large number of strains recovered from sewage or from patients towards the end of a cholera epidemic were found to be A-resistant; it was also known that the A phages had the power of changing a smooth vibrio into a rough one, and of reducing or abolishing the agglutinability of that vibrio. In other words, they could change a normally agglutinable cholera vibrio into one which had hitherto been regarded as a water- or non-cholera vibrio. One authority went so far as to say that not only would A phages urn a normal cholera vibrio into an unagglutinable one, but that B and C phages had the power to turn it back again to a pure normal bacterial culture of cholera vibrio. If that were true, immunologists had to combat not only the cholera vibrio, but also those phages which had the power of reconverting it from a harmless to a harmful organism. The observation, however, had still to be confirmed.

Prof. J. C. G. **Ledingham** criticised Dr. Burnet's theory. He knew of no crucial experiment that would prove it. Prof. J. Bordet had welcomed Dr. Burnet's work as supporting his own view that the phage was a manifestation of transmissible autolysis. Prof. Bordet had laid stress on the lysogenic properties in his Croonian lecture a year and a half ago, and had said that it was very difficult to eradicate them. On Dr. Burnet's showing the organism must have a virus, and possibly two or three viruses, associated chloral hydrate in lemonade, the drink being taken very slowly, otherwise vomiting might ensue. Two hours later nembutal grs. 1½ and a like quantity of chloral hydrate was given. Usually the labour had proceeded almost to the end by the time the second dose had been acting for an hour or so, so that the administration of gas-and-oxygen or chloroform for a short time was all that was needed. He had not noted, when using this means, that labour had been protracted particularly, nor had any of the babies been born with dangerous asphyxia. Among the chief drawbacks were the great variation in the action of the nembutal as between patient and patient, and the tendency to sickness of the mother. Avertin had its place in obstetrics; its action was the same as when it was used as a pre-operative narcotic and as safe, provided that the patient was not left alone. The dose for obstetrics should be three-quarters of the pre-operative dose, and should be given to primiparæ when the cervix was three-quarters to fully dilated, and to multiparæ at about half the full dilatation. In 20 cases he had had no difficulty about the rectal administration or retention of avertin. He had not met anyone who had had personal experience of the Gwathmey method.

THE PRACTITIONER'S POINT OF VIEW

Dr. GLYN HUGHES discussed the relative merits of the various forms of anæsthesia used in labour from the standpoint of the general practitioner, especially in view of the fact that half the labours of the country were conducted by midwives It was necessary to differentiate between practitioners working in London and those practising in out-of-the-way country districts. He did not advocate twilight sleep, as constant attention and supervision were required, and the child might be born apnœic But the modified method of giving smaller doses of morphia and scopolamine as a preliminary sedative could be very helpful. Pernocton and nembutal were uncertain in their effects, especially when given by the mouth, the only practicable method in obstetrics. Moreover their use was always followed by some degree of restlessness, which might be a serious handicap, and certainly wearied the patient and diminished the patient's expelling power. This restlessness could be to some extent diminished by giving beforehand an injection of omnopon and scopolamine. To have a child born in a condition of apnœa was always a worry to the practitioner. The difficulty in regard to paraldehyde was one of rectal retention; it was necessary to hold the buttocks together, a difficult matter in labour. Avertin he had never used in obstetric practice; its action was too short-lived to be of value to the general practitioner He agreed that all the drugs mentioned might be useful in institutions Gas-and-oxygen was of immense value, but was difficult to administer. Dr. Hughes was wholly in favour of chloroform as against ether, except where contra-indicated, as in toxæmia, hæmorrhage, and exophthalmic goitre. Ether introduced the risk of bronchitis Chloroform was particularly suitable for women who clamoured for some form of anæsthesia from the start Sleep and rest were a valuable preliminary to labour, and did much to prevent uterine inertia, shock, and post-partum hæmorrhage.

A FOOL-PROOF JUNKER

Dr. Z. MENNELL remarked that the expert obstetrician, the expert anæsthetist, and the general practitioner had been heard in the discussion, but not the midwife Granted that gas-and-oxygen was the ideal anæsthetic for labour, the ideal was unattainable in this country under existing circumstances. The result of a long experience in both practice and teaching was that chloroform, given to the obstetrical degree in normal labour, was the only feasible anæsthetic. It was a matter of general agreement that every effort should be made to ease the suffering associated with labour and to help the women at least to forget what they had gone through. By normal labour he meant one in which there was reasonable hope that the woman would deliver herself unaided; and by chloroform anæsthesia to an obstetrical degree he meant a light anæsthesia, really an analgesia, causing only partial amnesia And it should be intermittent. The degree of anæsthesia should be deepened slightly at the end He did not think the barbiturates were to be recommended in this class of work. Twilight sleep had been tried out in a long series of cases at St. Thomas's and all he would say about it was that hyoscine and morphia had their uses. Avertin he regarded as too uncertain to be useful, and if rectal anæsthesia was needed, some safer drug should be chosen The synergistic anæsthesia, or Gwathmey method, seemed to him to be complicated. He considered that paraldehyde, freshly mixed and given per rectum was one of the safest of analgesics; it greatly aided the earlier stages of labour and rendered the use of chloroform easier; it was not necessary to use large doses. Recently there had been talk of capsules of chloroform being issued to midwives, and in this he saw possible danger; it should be possible to produce a fool-proof Junker inhaler, and he showed one which he had nearly completed, which it was proposed to register. He thought candidates for the C.M.B. certificate should be required to show familiarity with it. Anæsthetists should face the fact that a large number of patients were delivered single-handed, and set to work to determine the safest form of analgesia. His own preference was for paraldehyde, with or without chloroform vapour from a Junker.

THE NEED FOR CAUTION

Sir WILLIAM WILLCOX warned the profession with regard to the use of certain drugs for producing anæsthesia, whether during labour or otherwise. Nembutal was a new drug, and the dangers of its use only became known after bitter experience It was the most powerful of the barbituric acid group from the toxic point of view, exceeding considerably the toxic power of luminal. Nembutal poisoned the kidney cells, stopped their secretion, and in consequence suppression of urine might occur. He knew of four cases of such suppression following its use which ended fatally, though the doses were smaller than those mentioned by Mr. Leslie Williams. Considerable hesitation was necessary before nurses were entrusted with a drug of such potency. Drugs of this class killed by causing what was known as veronal pneumonia, which he had described in 1913. No practitioner could keep abreast of the chemical and biochemical advances constantly going on, and he had to rely on information received through reputable channels; and the need for caution was all the greater in view of the large number of manufactured emanations for which many virtues were claimed. Sir William agreed with the principle laid down by Dr. Mennell, and urged the need to remember that a small dose could be doubled at will, but a big dose could not afterwards be withdrawn; gr. 1/6 of morphia and gr. 1/200 of scopolamine would harm no one.

Mr. J. P. **Hedley** agreed that, within limits, the less drugs the woman in labour was given the better. Paraldehyde was a safe drug to use. He was in accord with all that had been said concerning chloroform.

Dr. B. **Schlesinger** asked what method of anæsthesia in labour left the infant at its best; was not nembutal liable to leave the child cyanosed? Was chloroform safe for the infant?

Mr. D. M. **Roy** said that if one restrained a patient to whom nembutal had been given it was evident that the whole musculature was working. He assumed that when so much muscular energy was being expended there could not be the needed concentration on the expulsion of the child. It seemed a pity to use any method of inducing analgesia which minimised or did away with the coöperation of the woman; it should be possible to dull her pain without destroying her consciousness. Admittedly some women wished to be oblivious of the whole proceeding, but others preferred to know what was going forward.

Dr. **Jenner Hoskin** asked whether any modification of anæsthesia had been devised to suit mothers with damaged hearts who were passing through labour—i.e., mitral stenosis without definite failure.

Mr. W. **McKim McCullagh** said he was attached to a hospital at which 1600 deliveries were effected per annum, and all the various anæsthetics had been tried there. In the last five years the only death from anæsthesia was in a patient who was given chloroform, death resulting from atrophy of the liver. Morphia and magnesium sulphate has been tried, and no effect was traced to the magnesium sulphate.

Mr. W. **Gilliatt** did not think it would be denied that all anæsthetics delayed the uterine contractions. It was not wise to lead every mother to believe she would pass through a painless labour; rather she should be told it would be accompanied by pain, but that efforts would be made to lessen it. Then it would not be necessary to drug her throughout the labour. He had had no ill-effects from nembutal and chloral; there was an absence of excitement in the mother and of disquieting symptoms in the baby.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE

Bacteriophage

Dr. G. **Carmichael Low**, the President, took the chair at a meeting of this society held at Manson House on Jan. 19th, when Dr. F. M. **Burnet** read a paper on recent work on the Biological Nature of Bacteriophages.

He said that the active agent was particulate and varied considerably in size—between 10 and 60 μ—though the particles of a given phage were nearly always uniform in size, and the size was independent of the organism on which the phage was grown. The rate of inactivation by heat changed with the temperature in a fashion characteristic of the heat denaturation of proteins. The influence on heat inactivation of solutions containing different proportions of bivalent and monovalent kations indicated that the surface condition of phage was similar to that of bacteria and other living organisms, and that phages, even when purified by the elimination of bacterial antigens, were capable of inducing the formation of specific antibodies. All the evidence was therefore compatible with the view that the phage particles were definitely organised bodies reproducing themselves true to type, and largely composed of protein. Some of the large-particle phages strikingly resembled minute bacteria in their behaviour. True agglutination of washed phage particles could take place; non-multiplying bacteria could be coated with phage and then agglutinated specifically with anti-phage serum, and in the course of phage multiplication a specific soluble substance was produced which was separable from the phage particles by ultra-filtration, and could also react with the specific antibody of the phage serum. The problems of lysogenicity had great theoretical interest. Certain quite characteristic bacterial strains could, by certain manipulations, be used to induce typical lysis either of the homologous strain or of another. Apparently normal strains of coliform bacteria had regularly produced a phage lysing Shiga-dysentery cultures. Lysogenicity had been found surprisingly common in salmonella cultures, and a large number of phage types could be obtained from cultures of a single species. Lysogenicity was not an essential characteristic of the species. The relationship demonstrated could only exist between two sets of biological entities when their evolution and differentiation had been essentially independent. In other words, the phenomena of lysogenicity indicated that bacteriophage formed a group of independently evolved living organisms capable of entering into parasitic or symbiotic relationships with bacteria. Dr. Burnet concluded, therefore, that bacteriophages were independent micro-organisms, viruses which were obligate parasites or symbionts of bacteria. He suggested a classification according to particle or plaque size, serological character, and resistance type.

Colonel F. P. **Mackie** showed slides illustrating the methods in use in Bihar and Orissa and in Assam for the isolation and standardisation of bacteriophages, and for the detection and typing of natural and unknown phages by testing them against a series of phage cultures of different specific resistance. A large number of strains recovered from sewage or from patients towards the end of a cholera epidemic were found to be A-resistant; it was also known that the A phages had the power of changing a smooth vibrio into a rough one, and of reducing or abolishing the agglutinability of that vibrio. In other words, they could change a normally agglutinable cholera vibrio into one which had hitherto been regarded as a water- or non-cholera vibrio. One authority went so far as to say that not only would A phages urn a normal cholera vibrio into an unagglutinable one, but that B and C phages had the power to turn it back again to a pure normal bacterial culture of cholera vibrio. If that were true, immunologists had to combat not only the cholera vibrio, but also those phages which had the power of reconverting it from a harmless to a harmful organism. The observation, however, had still to be confirmed.

Prof. J. C. G. **Ledingham** criticised Dr. Burnet's theory. He knew of no crucial experiment that would prove it. Prof. J. Bordet had welcomed Dr. Burnet's work as supporting his own view that the phage was a manifestation of transmissible autolysis. Prof. Bordet had laid stress on the lysogenic properties in his Croonian lecture a year and a half ago, and had said that it was very difficult to eradicate them. On Dr. Burnet's showing the organism must have a virus, and possibly two or three viruses, associated with it. Prof. Ledingham found this difficult to believe, especially as it had been shown that the organism suffered no harm whatever. As the phage was an independent organism, it was difficult to see why various salmonella organisms were associated with specific phages, instead of the association being dictated by chance. The speaker considered that the salmonella organisms were closely related antigenetically, and that the variation in their phage content might be associated with that property. He could not see why the particles should vary so greatly in size; the various pock viruses, such as vaccinia, ectromelia, and cow-pox, varied hardly at all. Monomolecular inactivation by heat gave no relevant information. He appealed to workers in the East to state whether phages had a therapeutic action or not against plague, cholera, and similar diseases.

Dr. A. FELIX objected to Dr. Burnet's theory on the ground that, since both the phages and the bacterial antigen were colloids, they were not separable by a simple procedure like washing, and that the antigen, which could be adsorbed to the phage particles, might be responsible for the production of antibodies, which appeared to be specific since they did not react to the original antigen of the organism.

Prof. G. S. WILSON supported Dr. Burnet, saying that it was impossible to devise a crucial experiment to settle such a complicated biological problem. The question could only be settled by accumulated evidence. He asked whether lysogenetic strains had been found amongst organisms that had not been in contact with the intestinal canal or sewage. In bacterial cultures it was almost necessary to assume that every organism was infected with a virus, or else that there were special cells which were more or less susceptible to the virus or phage, and in which it could multiply to a certain extent without bringing about complete lysis of the organism. He asked whether Dr. Burnet believed that the association between the phage and the organism was in the nature of a symbiosis.

Prof. WARRINGTON YORKE reminded critics that, unlike a politician, a scientist had a right to change his mind.

Colonel MACKIE, in reply, said that the results of the two large field experiments in India had been wholly satisfactory from the point of view of those workers who had conducted them. Feeling at Calcutta was sharply divided for and against the efficacy of phage. The results of mass treatment in India had appeared extremely good, but an equal decline in incidence had taken place in neighbouring (control) districts and might have been due to an inter-epidemic period. There was some evidence that where bacteriophage had been given as a curative agent to members of households at epidemic times, there had been a notable reduction in incidence, but in some small local epidemics there had been no such reduction. The advocates of phage held that some races of it were still undiscovered and that therefore the mixture was not complete. A large-scale experiment should, he said, be done on herd and laboratory animals; human epidemics introduced so many variable factors that statistics based on them would long remain untrustworthy.

REVIEWS AND NOTICES OF BOOKS

The Early Diagnosis of the Acute Abdomen

Sixth edition. By ZACHARY COPE, B.A., M.D., M.S. Lond., F.R.C.S. Eng., Surgeon to St. Mary's Hospital, Paddington. London: Humphrey Milford, Oxford University Press. 1932. Pp. 247. 10*s*. 6*d*.

THIS useful book has reached a sixth edition. As a guide to student and practitioner in the early diagnosis of acute abdominal conditions it does all that a book can do to support clinical opinion with authority, and to remind the unwary of certain pitfalls. Mr. Cope maintains the position he has previously adopted in regard to the time of operation for acute appendicitis. He says "the view is accepted by most surgeons of experience that every case of acute appendicitis should be operated on within the first 24 hours from the onset or as soon after as is possible." A reiteration of this dogmatic teaching by a surgeon of Mr. Cope's experience would bring comfort to those who have been stirred by doubts on this difficult problem, had it not been qualified by his remark at a discussion at the Royal Society of Medicine that "to say that immediate operation should always be undertaken is not to give the clinician any credit for judgment." In the chapter on acute abdominal disease with genito-urinary symptoms we could find no mention of the cases of diverticulitis which have genito-urinary symptoms as their most striking feature. The chapter on diseases simulating the acute abdomen covers the ground fully, but, while cardiac failure, pericarditis, and angina pectoris are discussed from the point of view of differential diagnosis, no mention at all is made of coronary thrombosis, which is certainly the cardiac conditio most liable to be mistaken for an acute abdomina catastrophe.

This book should certainly be included in the library of every practitioner.

Diseases of the Thyroid Gland

Diagnosis and Treatment. By GEORGE CRILE an Associates. Edited by AMY F. ROWLAND. London W. B. Saunders Co., Ltd. 1932. Pp. 50 32*s*. 6*d*.

ANY work emanating from the Cleveland Clini on the subject of thyroid disease is sure of a welcom since the originality and enthusiasm of Dr. Cri and his co-workers arouse interest even if they d not always induce agreement. This book consis of a series of articles on the various aspects of thyroi disease by 24 contributors, and as is inevitable when large team collaborate, there is considerable inequalit in the merits of some of the articles. One of t best is the chapter on iodine and the thyroid glan by George Crile, Jun. This admirable summa of the subject has a good bibliography, and written in a pleasing style. A chapter on carl hydrate metabolism in hyperthyroidism, by Hen J. John, is a clear review of this much discus subject, and contains suggestive observations. D George Crile's chapters on such diverse matter the rôle of the thyroid gland in the energy syste endemic goitre, the adrenal factor in hyperthyroidis and thyroglossal fistulæ are written in his usu attractive way, and are full of stimulating ide One of the least satisfactory chapters is that routine technique of thyroidectomy, by Robert S. Dinsmore. To the inexperienced thyroid surgeon it can hardly make the steps of the operation clear, and to an expert it will seem full of dogmatism on controversial points. The book is well illustrated and is admirably produced.

Anatomy of the Brain and Spinal Cord

Second edition. By WILLIAM W. LOONEY, A.B., M.D., Professor of Anatomy, Baylor University College of Medicine, Dallas, Texas. Philadelphia: F. A. Davis Company. 1932. Pp. 370. $4.50.

THIS exposition of the most complicated branch of anatomy is planned for the medical student. The bed-rock of the subject is simply and dogmatically displayed along conventional lines; the blending of a certain amount of physiology with the anatomy is well done and increases the teaching value of the book. The diagrams and other illustrations in the text are adequate, and the print and paper are admirable. An unusual and practical feature is the short appendix, wherein a series of clinical cases are described to show how neurological diagnosis must rest upon accurate localisation of the lesion.

While the subject matter is sound enough, it might be brought more up to date in one or two respects without undue elaboration. For example, modern work on the localisation of the sympathetic centres in the hypothalamus is too important to be omitted from any text-book, however elementary. The book will be used with appreciation by students still in the dissecting-room as well as by their seniors revising for final examinations.

Medicinal and Poisonous Plants of Southern Africa

By JOHN MITCHELL WATT, M.B., Ch.B. Edin., Professor of Pharmacology in the University of the Witwatersrand, Johannesburg; and MARIA GERDINA BREYER-BRANDWIJK, Phil. docta. (Utrecht), Research Worker in Phyto-chemistry in the Department of Pharmacology in the University of Witwatersrand. Edinburgh: E. and S. Livingstone. 1932. Pp. 314. 25s.

WHILE in Europe most popular folk-remedies have been proved by pharmacological research to be useless, enough have been shown to be of value to warrant the systematic examination of those employed in other parts of the world. In Southern Africa, as is pointed out in the preface to this book, Bushmen, Hottentot, Bantu, and European have contributed to folk-medicine from the great wealth and variety of the flora of that country. Much of this lore is rapidly disappearing before the advancing tide of civilisation, with its synthetic medicines, and it is a matter of urgency that it should be sifted and placed on record before it finally disappears. This important work has been executed here in a careful manner. The authors have aimed at collecting all available information on the medicinal uses, chemical composition, pharmacological effects, and human and veterinary toxicology of the flora of Southern Africa, and have produced an excellent work of reference on the medicinal and poisonous plants of that country. The book provides extensive bibliographies and beautiful illustrations, some of them in colour, and the four elaborate indices, based on the botanical names of plants, the common names from European languages, the native names, and the names of active principles, make for easy reference. The authors are to be congratulated on their scholarship; they have supplied information difficult to get, which may be of importance in leading to the greater utilisation of the natural products of a sub-continent.

The Treasury of Human Inheritance

Nettleship Memorial Volume. Part V. (concluding section, pp. 425–555, with 18 plates). *On Some Hereditary Structural Anomalies of the Eye and on the Inheritance of Glaucoma.* By JULIA BELL, M.R.C.P., Francis Galton Laboratory for National Eugenics. London: Cambridge University Press. 1932. 36s.

IN this concluding section of the Nettleship Memorial Volume, Dr. Bell brings to an end her scholarly survey of the literature and pedigrees relating to hereditary anomalies and diseases of the eye. To those who are familiar with the previous sections it needs no recommendation. The conditions here taken up are such anomalies in the size of the eye as anophthalmos, microphthalmos, megalocornea, buphthalmos; anomalies in the development of the iris-aniridia and coloboma iridis; ectopia lentis and glaucoma. Consideration of hereditary nystagmus had, for lack of space, to be omitted, but Dr. Bell hopes it may be possible to take this up at a later date. For the present study over 300 pedigrees have been collected from unpublished and published sources, and are set out together with a very considerable amount of relative detail. The information which the extensive literature has yielded and the deductions to which it leads are discussed with the care and caution that are always associated with the Galton laboratory. Readers will note with regret that with this volume Prof. Karl Pearson brings his distinguished editorship of the series to a close, in view of his approaching retirement from the Galton chair.

The Life and Work of Lucy Bainbridge

By A. H. MCKINNEY, Ph.D., D.D. London, Edinburgh, and New York: Fleming H. Revell Company. 1932. Pp. 201. $2.00.

THE career dealt with in this small book was thoroughly worthy of record, for Lucy Seaman, afterwards Lucy Bainbridge, devoted her long life of 86 years to welfare work, much of which indirectly or directly was associated with medicine. To the end she was unceasing in her endeavours to mitigate suffering, which she began when during the American Civil War, as a young girl, she was a nurse in the army of the North. With one section of the troops she was well known as "Sister Ohio," and when the great Abraham Lincoln spoke to her she remembered that he made reference to her red hair. She also met General Grant, and later was able in one of her books—and she wrote several—to give a vivid picture of the two men. Through her close contact with Clara Barton, an early organiser of Red Cross work, whose life is sometimes compared in America to that of Florence Nightingale, she became acquainted with the conditions under which nursing was conducted some 50 years ago in the United States, especially in the more newly settled parts, and she has described in vivid terms the horrors of pioneer nursing when the women, practically untrained, could only obtain the most rudimentary equipment and when all the facilities of transport were absent. Marriage altered the immediate objectives of her work, but in no way led her to abate her energies which now were directed towards religious organisation. She travelled round the world, visiting mission stations in various countries, and was the leader of City Mission work in New York. The author of the book was himself formerly superintendent of the New York City Mission Society, while the well-known New York surgeon, William Seaman Bainbridge, is her son, so that on medical and social sides alike the biography appears with authority.

Preventive Medicine

Fourth edition. By MARK F. BOYD, M.D., M.S., C.P.H. London: W. B. Saunders Co., Ltd. 1932. Pp. 532. 22*s.* 6*d.*

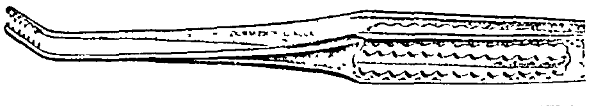
THIS book, primarily intended for American medical students and general practitioners of medicine, deals, in 37 chapters, with communicable diseases, deficiency diseases, occupational diseases, puerperal diseases, heredity in relation to disease, certain special problems of hygiene, vital statistics, and public health administration. The writer, having held a chair of bacteriology and preventive medicine, approaches the problems of public health from the scientific point of view. but sets out the information available in a simple and practical manner. The book is copiously illustrated; most of the illustrations are well reproduced, but some of them are perhaps unnecessary. The chapter on milk will be of special interest to sanitarians of this country at the present time: it will probably be news to some of them that chlorine for the sterilisation of milk utensils is now superseding steam in America. It is astonishing and a little disappointing to find practically no reference to the importance of what has been called latent epidemisation and latent immunisation in relation to the problems of epidemics, and the account of modern ideas in relation to the bacteriology of food poisoning is very sketchy. Ample references are supplied to American literature on public health and sanitation, especially to the publications of the various departments of the United States Government.

Dr. Maude Abbott's book on the History of Medicine in the Province of Quebec, reviewed in THE LANCET of Dec. 17th last, is a reprint, with additions and illustrations, of a collection of monographs hitherto only available in Canada. It can be obtained in this country from H. K. Lewis and Co. for 15*s.*

NEW INVENTIONS

UPPER FIXATION FORCEPS

THESE forceps are for fixing the eye in cataract extraction. One foot is placed on the upper limbus and the other 5 or 6 mm. higher up on the globe. They are then closed. This gathers up the intervening conjunctiva to the limbus, where it forms a fold or pleat held at its base in the forceps. This affords very good fixation. The corneo-scleral section is now made forthwith, the knife cutting out immediately behind the feet of the forceps—i.e., through the posterior layer of the conjunctival fold. This procedure makes a good conjunctival flap.



The forceps are made by Messrs. Down Bros., Ltd., St. Thomas's-street, London, S.E.

D. PRIESTLEY SMITH, M.B., Ch.B. Birm., M.R.C.S

REPORTS AND ANALYSES

PY-SHAN POINTS TEA

(THOMAS CHRISTY AND CO., 4, OLD SWAN-LANE, E.C.)

WE have analysed a sample of Py-shan Points tea with the following result:—

Moisture	7·2	per cent.
Ash	5·3	„ „
Total extract	45·6	„ „

The tea, when infused for five minutes with boiling water, yielded

Caffein	3·8	per cent.
Tannin	13·6	„ „

So far as analytical figures are concerned the inference may be drawn that the tea is one of good quality. The tannin content, to which importance is attached by some if it be high, is fairly low, the caffein and other constituents are normal. The tea itself is derived from selected tips of the pickings, and as a consequence the flavour of the infusion is not rough, but is soft and refined. This tea was analysed in THE LANCET laboratory 22 years ago, and it is noteworthy that during that long period its high quality has been maintained.

BOURNEMOUTH ORIGINAL SPA WATER

(THE SOUTH-WESTERN MINERAL WATER CO., LTD., SPRING-ROAD, BOURNEMOUTH)

We have had submitted to us a sample of this spa water for analysis and comment.

The water is derived from a deep artesian well, is colourless and odourless, and the dissolved carbonic acid gas imparts an agreeable and "fresh" sensation to the palate. When poured into the glass the excess of gas is liberated, producing a sparkling effect.

When analysed the following results were obtained:—

	Parts per 100,000.		Parts per 100,000.
Silica (SiO_2)	0·80	Soda (Na_2O) ..	7·95
Alumina (Al_2O_3) ..	2·55	Chlorine (Cl) ..	6·72
Iron (Fe_2O_3) ..	1·20	Sulphuric acid (SO_3)	17·50
Lime (CaO)	4·05	Total solids	42·40
Magnesia (MgO) ..	2·62	Free carbonic acid	22·00

These figures may be expressed in combination as follows:—

Silica	0·80	Calcium sulphate ..	[illegible]
Aluminium sulphate	7·40	Magnesium „ ..	7·86
Iron bicarbonate ..	1·80	Sodium „ ..	4·74
Calcium „ ..	2·29	Sodium chloride ..	11·10

The reaction of the water is faintly acid owing to the presence of free carbonic acid, on consumption however it would become alkaline. The mineral constituents are of interest, particularly the aluminium sulphate, which may have a slightly astringent effect; the bicarbonate of iron will be of use in cases of anæmia, and the sulphate of magnesium and sodium will tend to render the water aperient in character. The carbonic acid gas present is an undoubted aid to digestion, as this gas causes an earlier and more abundant secretion of gastric juice. The water is exceptionally pure, not heavily saline, and brilliant in appearance.

GLOVES FOR A MEDICAL OFFICER OF HEALTH.—At a meeting of the Prescot council's general purposes committee on Jan. 10th, Dr. S. M. Green, medical officer of health, was able to report that during the last month, among a population of about 12,000, there had been [illegible] deaths in the district, while the births had numbered [illegible]. Dr. Green was presented with a pair of gloves.

THE LANCET

LONDON: SATURDAY, JANUARY 28, 1933

MIGRAINE

WE publish in this issue the concluding part f a paper by Dr. MACDONALD CRITCHLEY and r. F. R. FERGUSON on migraine, a subject in hich many members of the medical profession ake more than an impersonal interest. There is urely no other disorder which reduces its victims, lbeit temporarily, to an equal degree of discomfort, incapacity, and indignity. The triviality f the sick headache—its very name a synonym or futility—usually prevents the sufferer from eceiving much sympathy. If the attack is evere he can only lie, more or less prostrate, n a darkened room, waiting impotently until t shall have run its course.

An excellent review of all aspects of the disrder, together with some four hundred references, as recently been published by H. A. RILEY.[1] t must be confessed that neither Drs. CRITCHLEY nd FERGUSON nor Dr. RILEY offer the sufferer nuch hope either of prevention or of cure. Neither rophylaxis nor treatment is likely to be completely uccessful until the causation of migraine is better nderstood. The question of ætiology comprises t least two distinct problems which can be nvestigated independently—the nature of the ocal disturbance of function responsible for the eadache and cerebral symptoms, and the chain f events leading up to this. Several recent nvestigations promise to illuminate the nature f headache in general and of migrainous headache n particular. G. W. PICKERING and W. HESS[2] ave lately sought to ascertain the mode of producion of headache by the intravenous injection of istamine. They made the interesting observaion that although histamine causes general vasoilatation associated with a rise of the pressure of he cerebro-spinal fluid, headache does not occur uring this phase, but only when the vasodilatation egins to decline; when it is at its height the pain an be temporarily abolished by a further injection f histamine. The cause of the headache induced y histamine is not yet clear, but there is lausibility in the view—one of two alternatives iscussed by PICKERING and HESS—that it is ue to an over-expansion of the cerebral arteries r arterioles, which for some reason only attains ts maximum after the preliminary vasodilatation as subsided. This hypothesis assumes additional nterest in view of F. HARE's observations, quoted by RILEY, on the effects upon the migrainous headache f compressing various arteries of the head and eck. HARE found that in unilateral migraine ressure upon the common carotid of the opposite side increased the pain, and in bilateral migraine pressure upon either common carotid removed the pain on the corresponding side and increased it upon the opposite side. He also found that in some cases it was possible to relieve or even to abolish the pain by compressing one of the superficial arteries of the scalp on the side of the headache. Unilateral headache in migraine is often associated with dilatation and increased pulsation of the superficial temporal artery on the same side. There is therefore considerable evidence that migrainous headache is associated with abnormal dilatation of the arteries of the head and can be temporarily abolished by diminishing the blood-flow through them. We do not know whether the pain arises directly from the distended vessels or whether it is an indirect result of their distension. That an increased pressure of cerebrospinal fluid is the cause of the pain is improbable for several reasons. There is evidence that the pressure of the fluid may be subnormal in migraine and in other states associated with headache—for example, following lumbar puncture and in some cases of head injury. Conversely, provided the leptomeninges are not inflamed, the pressure of the fluid may be considerably above normal without headache resulting—for example, in some cases of hydrocephalus. The cerebral blood-vessels are supplied with sensory nerves and appear to be sensitive to pain. It seems probable that they play a more important part in the production of headache than is generally suspected, even in conditions such as intracranial tumour where some other cause seems operative.

If the immediate cause of the headache in migraine is a temporary functional disturbance of the cranial blood-supply, how is this produced? The distinction of clinical types of migraine made by CRITCHLEY and FERGUSON is likely to be misleading if it is supposed that these types necessarily appear in different people. The same patient may at different times experience a large variety of attacks, headache, vomiting, ocular disturbances, paræsthesiæ, and mild confusion occurring in all possible combinations and also as isolated symptoms; and the attack may be traceable on different occasions to eyestrain, dietary indiscretion, menstruation, exposure to cold, or emotional stress. It is clear that all causes of migraine must possess in common the power to evoke a certain unknown state of the organism which is the immediate cause of the attack. Is there perhaps a toxin which, on the analogy of Sir THOMAS LEWIS's H-substance, may be called an M-substance, which is a by-product of metabolic, allergic, and other disturbances, and which produces a temporary disorder of the cranial blood-supply? Such a hypothesis is suggested by our present knowledge and may prove of value at least as a basis for future investigations.

Dr. CRITCHLEY and Dr. FERGUSON say that migraine is encountered in people of all types of intellectual ability, in all classes, and in all professions. Those of us who suffer from it, however, will continue to console ourselves with the classical teaching that it affects predominantly, if not exclusively, the most intelligent and sensitive members of the community. It is, we feel, a disharmony resulting from that exceptional development of the forebrain which differentiates man from the animals, and is thus the badge of a mental type which represents the highest point yet achieved in human evolution.

MANCHESTER AND MUNICIPAL POWERS

WE gave reasons last week for regretting that Manchester had defeated the proposal to ask Parliament for a local Act compelling the pasteurisation of milk. This was only one of several new powers desired by those responsible for the administration of a city which has been a pioneer in English public health. But even if the recent poll had given the town council a majority for its proposals (as on previous occasions), there would still remain the fight in Parliament. The clause for compulsory pasteurisation of milk has no English precedent, and the Select Committee on Local Legislation (if its critics may be believed) concerns itself more with the novelty than with the merits of such clauses. The Manchester incident may revive interest in suggestions which reformers have offered for the removal of the limitations on the powers of municipalities. Why, it is asked, should the town council of some great English city, comparable in wealth, population, and good administration with some of the independent States of Europe, have to resort to the slow and clumsy machinery of petitioning Parliament for a Local Bill whenever it is desired to extend some local service ? Why should the Victorian restrictions of the ultra vires doctrine, seemingly evolved in order to control the activities of statutory railway companies, be allowed to fetter municipal corporations ? It is anomalous and anachronistic, wrote a critic not long ago, that Birmingham is unable to carry on a milk-distributing trade, that the L.C.C. has never been allowed to help out its tramway system with omnibus services, and that Manchester must go cap in hand to Parliament for leave to undertake any trifling new activity, at great expense and with the possibility of being refused without reason assigned. One possible reform would be to reserve certain matters for national control and to allow the big cities to undertake any service belonging to public health or local government outside the matters expressly reserved. There is nowadays an object lesson in Ulster, where the Belfast legislature can deal with all non-reserved subjects. Similar devolution must be conceded some day to large-scale units of local administration in England, if only to relieve pressure on the Parliament at Westminster.

The problem unfortunately is usually attacked on the lines of party politics. The Local Authorities (Enabling) Bill, twice introduced in the House of Commons in the past six years, proposed to give the bigger local authorities liberty to conduct any business or undertaking which could come within the scope of a company incorporated under the Companies Act. The pros and cons of municipal trading are not t whole matter. There is at present too lit margin for experiment in local governme although improved standards of public healt have undoubtedly been attained by experime in progressive localities.

First of all, however, town councils which ai at pasteurisation or anything else that is ne must convince their constituent ratepayers Democracy must be persuaded to want what i ought to want. It was perhaps a tactical err to load the Manchester programme with as man as 15 different groups of proposals. Objecto to one group were evidently tempted to reje the whole programme. The results were surprising. One of the heaviest defeats was that of a seemingly innocent proposal as to elective auditor In fact, discrimination was inconspicuous; bu can democracy be expected to answer 15 questions at a time ?

◆

QUININE AND ITS SUCCESSORS

AFTER long preliminary inquiries the healt organisation of the League of Nations asked tho countries who favoured the holding of an International Quinine Conference to be supplied with particulars of the local prevalence and treatmen of malaria. The valuable information received from 93 health departments has now been codified and published.[1] Of the world's quinine, ove nine-tenths is made in Java and Sumatra, and about one-tenth in the Indian Empire, so that f all other countries the amount imported is a measure of what is used. There is one exception, that o Italy, where about 4000 kg. of quinine were mad in 1929, being a seventh of the estimated national need. The quinine imports of all countries during 1931 were 60,000 kg., whereas the estimated amount which would have been made had every malaria case received 20 g. annually would have been 1,387,000 kg. One example will emphasise this point. In India, out of 100 million cases—a moderate estimate—only from 8 to 10 millions are treated, and the amount of quinine distributed does not exceed 2·0 g. annually for each treated case. The remedy which seems obvious is the wid planting of cinchona ; but the matter is not s simple as that, for 50 years ago Ceylon exported 453,000,000 kg. of bark in one year, whereas no there are only 20 acres under cultivation there.

The problem is essentially economic, and mu light is thrown on it by a discussion which to place last June before the Royal Society of Tropic Medicine and Hygiene.[2] As Mr. T. A. HENRY, D.Sc then pointed out, what faces the Malaria Commission of the League of Nations is the attempt t discover some method of providing treatment f the very many victims of malaria who are too p to buy quinine, and whose governments cann afford to provide it free, or even to subsidise i adequate distribution. Colonel S. P. JAMES, wh d opened the discussion, showed how complex atment of the individual really is. There has be considered not only the question of plasmodial ecies, but of strain within the species. In primary ses of subtertian malaria a Roman strain has eded for control eight times as much quinine as n Indian one: a severe Madagascar strain is owerfully acted on by neosalvarsan, a mild Dutch ne but weakly. Important, too, is the stage of e-history, for the synthetic product plasmoquine effective against gametocytes but ineffective gainst schizonts: while another newly introduced nthetic product, atebrin, has a selective action gainst the schizonts of avian malaria—an action hich P. H. MANSON-BAHR has confirmed for a few ses in man. Again, the St. Mary's Hospital rophylactic experiment showed plasmoquine to e a good preventive of infection, acting presumably the early stages of the human cycle of the arasite—though unfortunately the daily dose eedful for full protection is too near the toxic dose r it to be taken for more than a few days at a time. urthermore, the effectiveness of drugs depends n a certain duration of infection; while, owing the fact that in natural conditions infection is ften seasonal, there is an apparent seasonal effect n their efficacy. This point has then to be borne n mind in comparing them; so, too, has variation n the constitution of different races of man. Lastly, s Prof. N. H. SWELLENGREBEL pointed out, a ystem of prophylaxis and treatment of proved alue may break down under the bites of many nfected mosquitoes, presumably because many porozoits are injected about the same time.

---

[1] Enquiry into the Quinine Requirements of Malarial Cou and the World Prevalence of Malaria. League of Nat Health Organisation. C.H./Malaria/185. Geneva. Dece 1932.

[2] Trans. Roy. Soc. Trop. Med. and Hyg., 1932, xxvi., 105; T THE LANCET, 1932, i., 1362.

Speaking on the production of synthetic drugs, rof. WERNER SCHULEMANN noted that it had never een the aim at Elberfeld to synthesise quinine, ut to produce new drugs with action on new and ifferent lines, and giving results which quinine ould not give, since it was there held that only on hose lines could laboratory research give progress. o far as concerns quinine, the outcome of the iscussion may probably be summed up in Sir DAVID PRAIN's view that the work on these synthetic rugs was such that it was no longer fair or justiiable to urge the further extension of cinchonarowing—significant coming from one with his reat experience of the cultivation. Nevertheless, here is at present no drug other than quinine which can be used in the mass to combat malaria ith any feeling of safety, and it is even possible hat the search for some synthetic product to take ts place may aid the cinchona industry: for the vidence seems convincing that it is not quinine ut some substance formed from, or by the stimu-ation of, quinine in the host's body which is urative. Should that unknown body be discovered n the laboratory, it will clearly depend on relative osts whether it is cheaper to produce it from omething else, or from cinchona bark. At all vents, the essence of the matter at the present ime is the question of costs. That the proposed nternational Quinine Conference should take place s clearly desirable. It will have many and mportant points to decide.

THE RETARDED CHILD

THE educational problem of the retarded child is one which, except in a few limited areas, has not seriously been faced in England. The Wood report of 1929, which ostensibly dealt with the narrower problem of the mental defective, demonstrated that, from the educational standpoint, the problem of the mental defective was but part of the wider problem of retardation in general, and recommended that the range of special school or class schemes should be correspondingly extended. In view of this report, it is interesting to read[1] of a system now in operation in Massachusetts which provides for the ascertainment and the education of all children retarded more than three years. Dr. DAYTON's article is written in commemoration of Dr. WALTER E. FERNALD, the initiator of the system, who organised its machinery and provided it with an elaborate scheme of examination. About 30 years ago Dr. FERNALD opened an out-patient department at his school for defectives at Waverley. Later this clinic became a travelling unit which visited schools and conducted examinations of retarded children. Finally, in 1919, a law was enacted making it obligatory for the school committee of each town to ascertain all children in attendance who were three years or more retarded, and also for special classes to be provided wherever there were ten or more such children. The requisite examinations were to be made by the State department of mental diseases, and sufficient travelling clinics have been established, staffed by hospital experts, to cover the whole State. The personnel of each travelling clinic is identical with that usually provided in this country for a child guidance clinic—viz., a psychiatrist, a psychologist, and a social worker; but much of the work assigned to the last is sometimes done by a school nurse or a teacher.

The examination itself is based upon FERNALD's well-known "ten-point scale," and, although its general lines are similar to those familiar in this country, it is probably seldom, if ever, that examinations of defectives are carried out here with so much elaboration and detailed inquiry. Family history, personal characteristics and social conduct, physical health, are all fully studied, and a psychological examination is carried out, utilising the Stanford-Binet scale. Incidentally, it is curious to note that there is no mention of the use of any performance tests. In this country, examinations of defectives for educational purposes are made usually by school medical officers who, in addition to their ordinary medical training, are expected by the Board of Education to have attended a short special course; but it is only in the larger town and city areas that medical officers obtain such opportunities of experience as will enable them to become expert in diagnosis, and it is notorious that the standards adopted in different areas of the country vary very widely. Only in a very few areas is there an official psychologist, and he has no standing in relation to the diagnosis of mental defect. It is quite certain that if ever there is to be provision for the retarded child in the wider sense on the lines suggested in the Wood report there will have to be some modification of the present procedure, and, in particular, a psychologist will have to find a place in the scheme.

---

[1] Niel A. Dayton, M.D., Director of Research for the Massachusetts State Department of Mental Diseases: The Walter E. Fernald Plan for the Examination of Retarded School-children, New Eng. Jour. Med., Nov. 24th, 1932.

We are approaching a time, if indeed we have not already reached it, when more attention will be given to the retarded, the nervous, the difficult, and the delinquent child. A number of experiments in dealing with the retarded by means of "opportunity" classes are in progress, while the movement for child guidance clinics is spreading rapidly. The best evidence of this widespread interest may be seen in the report of a week-end conference which appeared in last week's issue (p. 175). I the examination of these classes of childr a diagnosis of mental deficiency is alwa one of the possibilities; on the other han the certifying officer for defectives finds himse frequently confronted with cases of these oth types. It seems inevitable, therefore, th the personnel for the examination of defectiv should, in future, approximate to that required f these other purposes, and that indeed the personn of a child guidance clinic and of an educati committee for the examination of the retarde should be identical. It may, however, be questioned whether so elaborate a scheme of examination a that of Massachusetts will be practicable or eve in every case necessary.

ANNOTATIONS

TEACHING IN MUNICIPAL HOSPITALS

As the result of negotiations between the London Voluntary Hospitals Committee, appointed under Section 13 of the Local Government Act, 1929, and the London County Council, facilities for undergraduate teaching are to be available in certain of the Council's general hospitals. The plan is that for teaching purposes each of the London medical schools will be linked up with one or more London County Council hospitals. The teaching will be in the hands of the staff of the medical school, and since it is difficult to teach on patients whose treatment is not under the control of the teacher, the appointment of consultants to the municipal hospitals from among the staffs of the medical schools is obviously desirable. On the other hand, a medical officer attached to a municipal hospital would presumably be eligible for appointment as a recognised teacher of the University of London. Precise details of the scheme have not yet been worked out but are in process of settlement between Sir Frederick Menzies and the deans of the medical schools. Somewhat similar arrangements have long been in force in some of the hospitals formerly controlled by the guardians, and the idea is to develop and systematise these facilities. The value to students of the clinical material collected in the municipal hospitals can hardly be overrated, while the introduction of systematic teaching into the routine of municipal hospitals cannot fail to be a stimulation to the staff and indirectly to benefit the patients. The innovation, moreover, has historical importance as the first definite link to be established between municipal and voluntary hospital services. The development of these two services on completely independent lines would have been a calamity for the public as well as for the medical profession.

THE PRESCRIPTION OF THYROID

In the early days of the use of the thyroid glands of animals in medicine, liquid preparations made by extraction with media containing glycerin or alcohol were used. At a later stage, methods were devised for preparing a dry powder from the glands and for making this into compressed tablets. The strength of the tablets was expressed in terms of the equivalent of fresh gland, this representing the only possible means of standardisation at that time. The British Pharmacopœias of 1898 and 1914 described an unstandardised powder prepared from the thyroid glands of sheep, under the name of Thyroideum Siccum, this preparation being usually regarded as about five times as potent as an equivalent quantity of fresh gland. When the prescriber used a Pharmacopœial name, thyroideum siccum or dry thyroid, the dispenser was in no doubt as to his intention, but when the prescription was for tab. thyroid, thyroid extract, or thyroid gland, the dispenser was often uncertain whether the prescriber had in mind the Pharmacopœial preparation or the fresh gland and such prescriptions were often referred back fo elucidation. The unofficial British Pharmaceutica Codex, 1923, attempted to give some guidance o this point in the form of the following statement:—

> "Dry thyroid should be dispensed only when thyroideu siccum or dry thyroid is ordered; when thyroid, thyro gland, or thyroid extract is ordered, the dispenser shou supply the fresh gland or its equivalent (1/5) of dry thyr made up with milk sugar to the weight ordered."

The effect of this advice was that, when any doub arose, the patient received the smaller of the tw quantities which the prescription might possibly b interpreted to mean. For national health insuranc purposes the National Formulary expressed th doses of tab. thyroid gland in terms of fresh glan and recorded the corresponding doses of thyroid sic

Since thyroid is always handled by the dispens in the form of the dry powder, or the powder compressed into tablets, there appears to be no justification, except that of habit, for retaining the syste of prescribing thyroid in terms of fresh gland. I fact, the inclusion in the new Pharmacopœia of chemical method of standardising dry thyroid o the basis of its content of the active princip thyroxine, introduces complications in manufactu which add force to the objections arising from th possibility of ambiguity in reading prescription The British Pharmacopœia, 1932, describes, und the names "Thyroideum, Thyroid," a dry powd which has been standardised and adjusted to conta 0·1 per cent. of iodine in combination as thyroxin As alternative names, the synonyms thyroideu siccum, dry thyroid, thyroid extract, and thyro gland are applied to this preparation. These inclu all the usual names employed in prescribing thyro and it is for the prescriber to note that a prescripti written with any of these names must be interpret by the dispenser to imply that the thyroid of t Pharmacopœia is intended. Prescribers who ha been accustomed to think in terms of fresh gland a who continue to write their prescriptions on th basis will run the risk of their patients receivi out five times the quantity of thyroid intended, less they make it perfectly clear that the dose ated means fresh gland. But this method of escribing should now become obsolete: the stan- rdised Pharmacopœial preparation is the obvious sis for prescribing thyroid, and practitioners will wise to accustom themselves to write their pre- riptions on that basis. Manufacturers now express e dosage of their tablets in terms of the Pharma- pœial thyroid, and it is expected that in the new ition of the National Formulary the same basis of sage will be adopted.

PROGNOSIS IN CORONARY THROMBOSIS

ON the day before his death from coronary throm- osis Dr. Carey Coombs corrected the proofs of a aper on prognosis in this disease, and it appears the current issue of the *Bristol Medico-Chirurgical* ournal (p. 277). It is an amplification of that read the centenary meeting of the British Medical ssociation last summer, and deals with 144 cases oserved by Dr. Coombs. Of this number 49, or oughly one-third, died in, or soon after, the attack, nd of the survivors another third died within 12 onths. Age was found to be of some significance in rognosis, since 67 per cent. of those under 60 survived he attack, whereas the attack was fatal in 58 per ent. of those over 70. Sex had very little influence n prognosis, the outlook being slightly more favour- ble in males. There was no relationship between a istory of previous angina and the immediate or emote result; but in those cases in which the pain as abdominal in the attack the outlook was not uite so good as in those in which the pain was oracic, as is more usual. The important fact which merges from this study is that the prime factor in rognosis is the severity of the attack itself. This is ifficult to assess except from the consideration of the unctional efficiency of the heart as revealed by the ulse pressure. In this series 70 per cent. of those atients whose pulse pressure fell to 25 per cent. of the ystolic pressure or less died in, or within a short time f, the attack, and all were dead within a year. Unfortunately the converse, that all patients with a ide pulse pressure recover, does not hold true. One ther factor is of value in estimating the degree of ardiac damage, and thus the outlook for the patient, nd that is the occurrence of pericardial friction. his was heard in 42 cases, and of these 43 per cent. ied in the attack and a further 30 per cent. of the urvivors within 12 months, whereas the figures for hose patients in whom no rub was heard were 25 er cent. and 41 per cent. respectively.

The question of the outlook in coronary thrombosis s one of the most baffling problems in the whole of rognosis, while this paper recalls the loss sustained y the Bristol Medical School.

PHOTOGRAPHY IN THE INFRA-RED

PHOTOGRAPHY by infra-red radiations is one of he most interesting modern developments of the rt. Attempts to manufacture emulsions sensitive o infra-red rays date back to Herschel's experiments n 1840, but the preparation of this material has only ecome practically possible with the introduction f the cyanine group of dyes. Messrs. Ilford have ecently discovered a new dye which would allow he preparation of an emulsion of considerably igher speed and greater cleanliness in processing han its predecessors, and are eagerly working to render it even faster, and also to extend its range beyond the 9000 Å which is its present limit. At a meeting of the Royal Society of Arts on Jan. 18th Mr. Olaf Bloch, head of the research laboratories at Ilford, and president of the Photographic Society, reviewed the progress so far made.

The application of infra-red photography to medicine has hardly been explored, but one or two interesting possibilities are suggested. For instance, pathological changes in the myocardium have been illustrated clearly by post-mortem photography. Attempts have been made to photograph soft tissues by the infra-red rays transmitted through them, but the scatter is great and little detail is available in the prints. A photograph of the hand taken by the rays, to which it is slightly transparent, showed little beyond the outline. The infra-red rays, of course, are even longer than the rays of light, and have no penetrating power to compare with even the longest X rays. Mr. Bloch reported that photographs taken in Denmark of a case of lupus showed distinction between dead skin, tissue with lupus nodules in it, and healthy tissue. Results on the diagnosis of skin complaints and of such diseases as produce markings on the skin have not been very promising, but may still yield information of value. The lecturer showed a photograph which must already have attracted the attention of ethnologists: a man who when photographed by ordinary methods appeared to be a typical negro of deep colouring, showed on the infra-red sensitive photograph a surprising modification both of tint and feature which suggested strongly a Mongolian element in his heredity. The new photographs, when compared with orthodox ones of the same subjects, show a startling difference in the modelling of the features and the complexion, and this property may find an application to police work. Black fabrics suitable for use in the tropics can be chosen by their property of reflecting instead of absorbing infra-red rays; the new prints have shown great variation in this property between fabrics which to the eye seem to be of exactly the same hue.

PROLAN AND CANCER

PROLAN is one of the names given to the gonadotropic hormone, secreted by the anterior lobe of the pituitary, which controls the ovarian cycle and induces ripening of the follicles and luteinisation. Whether prolan is one hormone producing these two different processes or whether it consists of two different hormones, one, A, producing maturation, the other, B, luteinisation, is not yet certain. Nor is it clear whether the substance which can be prepared from the urine of pregnant women, and which has the same physiological effect on the ovarian functions, is identical with the hormone prepared from the pituitary, or only closely allied to it, having possibly undergone a slight chemical alteration.[1] What is certain is that while the urine of normal women contains only small amounts of this hormone, there is a great increase during pregnancy. This, indeed, constitutes the basis of the Aschheim-Zondek test for pregnancy. While the urine of normal women contains about 5 mouse units per litre that of pregnant women contains as much as 3000–5000 units. From this it was a natural step to pass from normal to pathological pregnancies, and to study the excretion of prolan in such conditions as hydatidiform mole and chorion epithelioma. In these conditions B.

---

[1] This question was referred to by Prof. W. Schoeller in THE LANCET of Jan. 7th, p. 40.

Zondek[2] found a great increase in the prolan content of the urine, equalling and even exceeding that found in pregnancy. What is more remarkable is that similarly large amounts of prolan are excreted in the urine of males suffering from testicular chorion epithelioma. In other testicular tumours an increased, though less marked, excretion of prolan has often been found, and Zondek states that "the presence of the follicle-maturing hormone in the urine of men should arouse suspicion of a malignant testicular tumour." This has been confirmed recently in America by R. S. Ferguson,[3] who in an abstract of Zondek's paper states, on the basis of 100 cases of testicular tumours, that in chorion epithelioma the average excretion is approximately 50,000 mouse units per litre, in embryonal adenocarcinoma 10,000–40,000 units, in embryonal carcinoma with lymphoid stroma 2000–10,000 units, in seminoma 400–2000 units, and in teratoma of mixed structure mainly of adult type 50–500 units.

Zondek was thus led to investigate the prolan excretion in patients with other types of tumours, and has recently summarised his results in English in a paper[4] read at the meeting of the American Gynecological Society. The increase in the prolan excretion was found to be much less striking and less common. It was observed in 80 per cent. of women with genital tumours, but the increase amounted only to from 20 to 30 times the normal physiological amount; or, expressed in mouse units, to 100–150. Moreover it was found not only in malignant but also in benign genital tumours. In women with extragenital tumours it occurred in only 36 per cent. of all cases. It is also pointed out that the urine from all these cases, when it is active at all, produces only maturation of the follicle and not luteinisation. An increased prolan excretion has not so far been found in the urine of men with cancer of the prostate. Whether the test for prolan is sufficiently delicate to indicate such relatively small differences in the prolan content of urine is a subject for further investigation. It is clear at any rate that the increased excretion of prolan depends primarily on the type of tumour and, secondly, on its site, and cannot at present be considered as a general reaction to the presence of malignancy. The reason why tumours of the sex glands particularly influence the prolan excretion may perhaps be found in the fact that while the pituitary regulates the functional activity of the sex glands, the latter are also capable of influencing the pituitary. Thus castration produces, as S. Fichera showed in 1905, very definite changes in the anterior lobe of the pituitary. This has been confirmed repeatedly, and has been demonstrated by J. Tandler and S. Grosz (1907) and others also in castrated men and women. J. C. Mottram and W. Cramer (1923) have found that similar but even more extensive changes in the pituitary, affecting not only the pars anterior but also the pars intermedia and the pars posterior, occur when atrophy—even partial atrophy—of the seminiferous tubules is produced by *irradiating the testis*. Under these conditions the interstitial cells hypertrophy. Zondek noted that castration produced an increased excretion of prolan not only in women but even in men. It seems possible, therefore, that the increase in the prolan excretion in tumours of the genital organs, other than chorion epithelioma, may be due, partly at any rate, to an impairment of the function of these organs produced by the destructive effect of the growth of the neoplasms, and that patholog conditions of the genital organs, other than tum but involving an interference with functi may also lead to an increased prolan excretion.

The most sensational development of this line of investigation is the claim made in a recent paper by B. and H. Zondek and W. Hartoch[5] that it is possible to inhibit the growth of a transplantable mouse carcinoma by repeated injections of massive doses of prolan. Unfortunately the data given in the paper are too incomplete to enable the reader to form a critical judgment. There are not even figures illustrating the histological appearances of the prolan-treated tumours. What is particularly difficult to understand is the statement that after transplantation of a tumour from a prolan-treated mouse into normal mice, which received no further treatment with prolan, the tumour continued to grow slowly, and that a second transplantation into normal mice further diminished the rate of growth. Clinical experience on the effect of pregnancy—where there is an intense physiological prolanæmia—on cancer does not support the idea that prolan inhibits the rate of growth of a malignant neoplasm, either in the human subject or in mice. If an inhibition of tumour growth takes place in pregnancy it is as an exception and not as a rule. It will be advisable, therefore, to await further confirmation of the experimental findings of Zondek and his collaborators on the alleged therapeutic effect of prolan in cancer.

COMPOUND FRACTURES OF THE LOWER LIMB

THE New South Wales branch of the British Medical Association recently held a special meeting to consider compound fractures of the lower limb. Subsequently the *Medical Journal of Australia* (1932, ii., 497, 515) published two opening papers read by surgeons of the Sydney hospitals, and in the same issue commented generally on the treatment of these fractures.

The discussion was an important one and deserves attention from those who, either as staff surgeons or residents, have charge of fracture cases in hospital. Emphasis was laid especially on the responsibility which rests on the surgeon of giving personal care and supervision to every fracture coming under his charge, and of regarding compound fractures as urgent surgical emergencies. Dr. John Hoets and Dr. George Bell, in the opening papers, both spoke of the very great importance of early and efficient treatment in the prevention of infection. Bell put compound fractures in the same category of urgent emergencies as ruptured peptic ulcers; early and efficient treatment, he said, involves excision of the wound (the so-called débridement) within 12 hours of the injury, and thorough cleansing to its depths. The comparative merits and special indications for primary suture and Carrel-Dakin methods of wound drainage and lavage were freely discussed. The protection of young granulation tissue in compound fractures from the trauma resulting from frequent dressings and too active "open" methods of treatment we have only lately begun to appreciate at its true importance. The ideal now is the conversion of an open into a closed fracture. Where the ideal method is not available, as when the time elapsing between injury and operation is 48 hours or over. or when the mechanical difficulties are too great, there is a choice of eith rel-Dakin methods, or of Winnet Orr's closed ster method. The surgical practice of Sydney races both, but the surgeons there seem to prefer Carrel-Dakin. As Hoets puts it: "good results y be obtained in many ways, and also bad results y be obtained when good methods are used badly."

uggestions were made for improvement in methods handling of patients between the arrival of the oulance and the delivery of the patient to operating theatre. It was urged that Thomas's nts should be carried by all ambulances, and t the bearers should be trained in their use. Dr. ets strongly advocated that the patient should be en straight from the ambulance to the bed in a iscitation ward, missing out the casualty depart- nt. The question was raised as to how far complete iscitation methods, as used in the base hospitals ing the late war, were available in modern pitals at a moment's notice, and this is a stion into which surgeons would do well to inquire.

MATERNAL DIABETES AND FŒTAL DEVELOPMENT

T is well recognised that diabetes in the mother l often prevent conception, cause abortion, or ult in the birth of a small and feeble infant. An parently contradictory observation has also been de frequently enough to exclude coincidence— nely, that diabetic women are particularly liable be the mothers of overweight infants. It appears, refore, that under different circumstances fœtal elopment may be influenced either favourably unfavourably by maternal diabetes. Dr. Hans [1] suggests that while a considerable elevation of blood-sugar will tend to destroy the fœtus, a derate rise may stimulate its development to an normal extent. He gives figures with reference to birth-weights of children of 192 women between ages of 30 and 65 in whom diabetes had been gnosed from one month to five years previously; ldbirth had occurred in many instances some rs before the diagnosis was made. Of these men, 37 had borne no children, and 30 (19 per cent.) l borne children who were well above the normal ight. A total of 155 women had had 608 children, which 63 per cent. were of average weight at th, 18 per cent. weighed eight pounds, and nearly er cent. weighed nine pounds. Of the remaining children, 49 weighed ten pounds and 17 ten to elve pounds, *giving a percentage of 10·8 of* "verweight" children. (These figures he compares h W. Zangemeister's,[2] who in an extensive study the infants of normal women found 3·4 per cent. ghing between eight and ten pounds, and only 6 per cent. over ten pounds.) He emphasises observation that not only women with proved betes are liable to bear overweight children, but o women in whom the diabetic condition is not ly established until later years. From this the gestion follows that an overweight child may resent the first manifestation of a latent diabetes, l Bix quotes several cases in which a raised blood- ar during pregnancy was unaccompanied by the earance of sugar in the urine. In two cases a ent diabetic condition was discovered by reason the abnormal weight of the infant. For this son he urges the importance of investigating the ar tolerance of all women giving birth to abnor- lly large infants, and even where the initial tolerance tests prove normal recommends that the patients should be kept under observation for a long time to prevent a latent diabetes being overlooked. In many of his own cases diabetic symptoms did not develop until more than ten years after the birth of an overweight child.

SERUM TREATMENT OF CEREBRO-SPINAL FEVER

WE are again approaching the time of year at which the incidence of cerebro-spinal fever is usually maximal, and the Ministry of Health is anxious to secure accurate data concerning the efficiency and potency of the serums used against the infection. As was pointed out in its "Review of Cerebro-spinal Fever,"[1] the most valuable test is clinical, and as it rarely happens that any one hospital has sufficient cases for useful differential study, the Ministry "is now endeavouring by means of individual case inquiry to collect and examine all evidence available regarding the results of serum treatment, both as to the methods of administration and as to the nature of the serum used." The coöperation of medical officers of health, hospital medical officers, and medical practitioners is invited, and report forms may be had from the senior medical officer, Med. I., Ministry of Health, Whitehall, London, S.W. 1.

REPRIEVE FROM BLINDNESS

IN ophthalmic surgery sensational cures are rare, but a case published by Mr. Herbert Fisher in the *British Journal of Ophthalmology* for January merits this description. Mr. Fisher, who has himself retired from active practice, publishes the case as an encouragement to those of his colleagues who may be prepared to follow his bold treatment of an apparently hopeless case. A boy developed sympathetic ophthalmia as the result of an accident at the age of 11. The injured eye was removed about four or five weeks after the accident. Sympathetic disease in the remaining eye ensued, and two years after the accident, in May, 1921, the patient first came under the care of Mr. Fisher at Moorfields Hospital. At that time the boy could only perceive light. There was still deep injection and much gross keratitis punctata, total posterior synechiæ, and an occluded pupil from inflammatory exudation over the lens capsule with diminished tension—a pretty hopeless condition on which few ophthalmic surgeons would give other than a bad prognosis. After a course of arsenical injection and a six months' continuance of hot bathings, atropine, and mercury by the mouth, all of which had little effect, unless it was to bring the blood count more nearly to normal, the patient was left practically without treatment for five years, during which time he was educated at a blind school. At the age of 18, seven years after the original accident, he was readmitted to Moorfields Hospital. The sight was then no better than perception of light with uncertain projection to the nasal side. Under a general anæsthetic Mr. Fisher first attempted an upper iridectomy and then a scoop extraction of the lens, without success. Finally he inserted a capsule forceps, one blade into the anterior chamber, the other into the posterior, and thus grasping the lens between its teeth at last succeeded in dragging it out together with the fibrous material in which it was enclosed. This heroic treatment was followed by no unfavourable reaction though, the iris becoming completely updrawn, the eye remained blind. Five months later, however, again under a general anæsthetic, Mr. Fisher performed an iridotomy with de Wecker's scissors, resulting in a centrally placed artificial pupil with vision improved to finger counting at 18 inches, which a year later had improved to 6/36. This vision, obtained in May, 1927, has since been maintained, so that the former pupil of a blind school is now living the life of an ordinary sighted person. In reporting this case Mr. Fisher emphasises three points: (1) the extreme loyalty of the patient and of his mother in not giving up hope of a cure through so many years; (2) from the outset Mr. Fisher had insisted on a long period of years before any operative procedure was attempted; (3) in the end the eye tolerated the violent interference which alone could accomplish any useful results.

THE ALLEVIATION OF LABOUR PAINS

THE great variation in the methods by which obstetricians are attempting to satisfy the public demand for alleviation of normal labour pains is encouraging in so far as it shows active research, but is in itself a proof of what we are weary of hearing—that no ideal anæsthetic for this purpose has yet been found. The question arises whether we are asking too much. At the discussion reported on page 199, Dr. Belfrage spoke of the hope that a method would be found as perfect as that already attained for surgical operations. From the anæsthetic point of view, however, the birth of a child is essentially a physiological operation which differs from surgical operations mainly in the following respects. It may last four or five times as long as any ordinary operation, and cannot be hurried without risk. Skilled medical attention is not, as a rule, available throughout the period, and the pain for which alleviation is sought is intermittent, not continuous. Voluntary muscular effort is required at certain stages of the process, and the patient's welfare is not the sole consideration, since the birth of a partially asphyxiated child may occur, as occasionally after twilight sleep, when the mother's condition has given no anxiety. The search for an effective analgesic which acts over long periods, can be administered safely by a midwife without elaborate or expensive apparatus, does not lessen the involuntary uterine contractions or completely remove the patient's power to assist expulsion by muscular efforts, may well be unsuccessful. Therefore we cannot agree with Mr. Roques (see p. 177) that we must necessarily await the discovery of this ideal anæsthetic before we sanction the use by midwives, with suitable safeguards, of such preparations as are deemed safe in their hands, even if these are not potent enough to do more than diminish the pain. Chloroform capsules are now under trial, and certainly appear to provide a nearer approach to what is wanted than any other device, though they have not escaped criticism.[1] Gas-and-oxygen is generally held to have the advantage over chloroform that uterine contractions are unaffected by its use, but Mr. W. Gilliatt did not except even this drug from his dictum that all anæsthetics inhibit contractions (see p. 201). It seems obvious, from the attention given to this subject of recent years, that the demand for less painful labour will become more and more insistent, and that the public are more interested in the solution of this problem than in any obstetric development, including even the reduction of maternal mortality and morbidity.

VITAL STATISTICS FOR 1932

THE Registrar-General has issued a provisional statement of the figures for birth-rate, death-rate, and infant mortality during the year 1932.

—	Birth-rate.	Death-rate.	Infant mortality rate.
England and Wales..	15·3	12·0	65
118 county boroughs and great towns including London ..	15·4	11·8	68
126 smaller towns ..	15·4	10·8	57
London (administrative county)	14·3	12·3	66

The smaller towns are those with estimated resident populations of 25,000–50,000 at the 1931 census. The birth- and death-rates for England and Wales relate to the total population and are calculated on the estimated mid-1932 population. The remaining rates are calculated on the estimated mid-1931 resident population, and relate to the total population for births, but to the civil population only for deaths.

The Registrar-General remarks that for the fourth year in succession the birth-rate is the lowest on record, being 1·0 per 1000 below that of 1929 and 1930, and 0·5 below that of 1931. The death-rate is 0·3 per 1000, and the infant mortality-rate 1·0 per 1000, below that for 1931. The only year showing a lower rate is 1930. In 1928 the rate was the same—namely, 65.

Mr. H. J. Simmonds, formerly legal adviser to the Board of Education, has been appointed to act as secretary of the inquiry into the affairs of the University of Durham College of Medicine, Newcastle, which is to be held shortly by Sir Amherst Selby-Bigge.

THE third International Pædiatric Conference will be held in London from July 20th–22nd under the presidency of Dr. G. F. Still. The proceedings will include general discussions on the Nature of Allergy and its Rôle in Diseases of Children, and the Prophylaxis of Milk-borne Diseases. Members who wish to make communications should inform their international committees, the secretary of the British committee being Dr. Leonard Findlay, 61, Harley-street, London, W.1.

INDEX TO "THE LANCET," VOL. II., 1932

THE Index and Title-page to Vol. II., 1932, which was completed with the issue of Dec. 31st, is now in preparation. A copy will be sent gratis to subscribers on receipt of a post-card addressed to the Manager of THE LANCET, 7, Adam-street, Adelphi, London, W.C.2. Subscribers who have not already indicated their desire to receive Indexes regularly as published should do so now.

STAMPS FOR A CONTRIBUTORY SCHEME.—The Merseyside Hospitals Council, which collects [illegible] £10,000 a year from 33,000 contributors, has adopted a simplified scheme of collecting the money. The contributors are being supplied with cards similar to national health insurance cards, upon which they will affix stamps varying in value from 1*d.* to 5*d.*, purchasable at the various depots. The stamps will be placed on the cards and cancelled with a date stamp. By this system labour will be saved and book-keeping simplified.

SPECIAL ARTICLES

E EPIDEMIOLOGICAL FEATURES OF WHOOPING-COUGH

A STATISTICAL INVESTIGATION

BY PERCY STOCKS, M.D. CAMB., D.P.H.
R IN MEDICAL STATISTICS IN THE UNIVERSITY OF LONDON,
AT THE GALTON LABORATORY, UNIVERSITY COLLEGE

PART I.

RHAPS no serious epidemic disease has suffered neglect by research workers as whooping-cough, it is mainly our ignorance of its epidemiology he consequent scant reference to it in the course edical training which accounts for the apathy e average practising physician and the lack of est of most medical officers of health in regard .

a paper elsewhere[1] I have tried to emphasise act that whooping-cough in London must now egarded as the most expensive epidemic disease ildhood when the cost is measured in terms of of life, acuteness of physical suffering, permanent age to respiratory, cardiac, or nervous mechanism, loss of school attendance, and not in terms of ey spent in efforts to combat it. Analysis of available London notification records have there shown to lead to the broad conclusions that e-fifths of all children born in London have oping-cough at some time, and that the periodicity pidemics might be determined by the occurrence temporary latent immunisation sufficient to ler between one and four children immune to each l who suffers a manifest attack, such immunity ppearing for the most part by the end of one year its acquisition.

the present paper a few additional observations made on the sex- and age-incidence of whooping-gh in London, its probable incubation period, its smission in houses, streets, and schools, and the sures of control which might prove efficacious reducing its ravages. For the data used I am bted to the medical officers of health of Battersea, enwich, Holborn, and Wandsworth, where the ase is notifiable, who have rendered every possible stance by placing the original records at my osal. My thanks to the school medical department he London County Council are expressed later.

Incidence by Sex and Age

he unusual sex ratio in whooping-cough has been ubject of comment for a long time. Statistics of rtality have been analysed by Laing and Hay[2] Aberdeen, by Crum[3] for the United States of erica registration area, by Godfrey[4] for New York te, by Hay and Russell[5] for London and Glasgow, and by Stevenson[6] for England and Wales, and all agree in showing an excessive mortality-rate in girls as compared with boys. At ages under 5 the ratio of female to male mortality-rates was about 1·07 in Aberdeen (1891–1900), 1·12 in Glasgow (1891–1900), 1·20 in London (1911–14), 1·22 in the United States registration area (1900–19), and 1·31 in England and Wales (1911). It was also shown by Hay and Russell[5] that the ratio increases from the first to the fifth year of life, thus :—

Age	0–	1–	2–	3–	4–
London, 1911–14	1·09 ..	1·25 ..	1·37 ..	1·52 ..	1·82
U.S.A., 1900–19	1·09 ..	1·41 ..	1·45 ..	1·56 ..	1·59

These figures refer to mortality, but the incidence of whooping-cough is also greater amongst females than males. It has been shown by Crum[3] from the Aberdeen data, and by Godfrey[4] from notification data in New York State that the ratio of female to male incidence is apparently higher at ages over 10, or over 15, than for younger children, but it has not been clearly demonstrated at what age the ratio begins to increase. I have therefore analysed in Table I. the data relating to some 15,000 notified and reported cases in Greenwich 1919–29, Battersea 1925–30, Wandsworth 1926–28, and Holborn 1921–28, as regards the age- and sex-distribution.

The ratios between numbers of cases need correction owing to the changes with age in the sex ratio in the living population, and this has been done in the last lines in the Table, which shows the ratios between the rates of incidence based upon the census populations of 1921, weighting the population of each borough by the total numbers of cases reported, since the period covered was not the same in each. It is evident that the sex ratio at ages up to 4 years was about 1·05, or 5 per cent. greater in girls ; it then increased to 1·2, or an excess of 20 per cent., by the eighth year, and to 1·5, or 50 per cent. excess, by the tenth year. In adults the ratio was as high as 3 to 1, but this may be partly due to deliberate concealment of the disease by men. Godfrey's figures for New York State in 1913–26 showed a ratio, between numbers of cases, about unity in the first two years, about 1·05 from 2 to 14, 1·2 at 15 to 19, and 2·3 at ages over 20, but from the London data it would appear that there is a significantly greater susceptibility of female infants from birth, and that the contrast increases from the fourth year onwards.

Seasonal Difference in Sex Ratio in Greenwich

It has not been ascertained, as far as I am aware, whether the sex ratio is more abnormal during certain seasons of the year than others. Analysis of the Greenwich cases during the decade 1919–29 according

TABLE I

—	Age-group—												Total.
	0–	1–	2–	3–	4–	5–	6–	7–	8–	9–	10–15.	15 and over.

was followed by no unfavourable reaction though, the iris becoming completely updrawn. the eye remained blind. Five months later, however, again under a general anæsthetic, Mr. Fisher performed an iridotomy with de Wecker's scissors, resulting in a centrally placed artificial pupil with vision improved to finger counting at 18 inches, which a year later had improved to 6/36. This vision, obtained in May, 1927, has since been maintained, so that the *former pupil of a blind school is now living the life* of an ordinary sighted person. In reporting this case Mr. Fisher emphasises three points: (1) the extreme loyalty of the patient and of his mother in not giving up hope of a cure through so many years; (2) from the outset Mr. Fisher had insisted on a long period of years before any operative procedure was attempted; (3) in the end the eye tolerated the violent interference which alone could accomplish any useful results.

THE ALLEVIATION OF LABOUR PAINS.

The great variation in the methods by which obstetricians are attempting to satisfy the public demand for alleviation of normal labour pains is encouraging in so far as it shows active research, but is in itself a proof of what we are weary of hearing—that no ideal anæsthetic for this purpose has yet been found. The question arises whether we are asking too much. At the discussion reported on page 199, Dr. Belfrage spoke of the hope that a method would be found as perfect as that already attained for surgical operations. From the anæsthetic point of view, however, the birth of a child is essentially a physiological operation which differs from surgical operations mainly in the following respects. It may last four or five times as long as any ordinary operation, and cannot be hurried without risk. Skilled medical attention is not, as a rule, available throughout the period, and the pain for which alleviation is sought is intermittent, not continuous. Voluntary muscular effort is required at certain stages of the process, and the patient's welfare is not the sole consideration, since the birth of a partially asphyxiated child may occur, as occasionally after twilight sleep, when the mother's condition has given no anxiety. The search for an effective analgesic which acts over long periods, can be administered safely by a midwife without elaborate or expensive apparatus, does not lessen the involuntary uterine contractions or completely remove the patient's power to assist expulsion by muscular efforts, may well be unsuccessful. Therefore we cannot agree with Mr. Roques (see p. 177) that we must necessarily await the discovery of this ideal anæsthetic before we sanction the use by midwives, with suitable safeguards, of such preparations as are deemed safe in their hands, even if these are not potent enough to do more than diminish the pain. Chloroform capsules are now under trial, and certainly appear to provide a nearer approach to what is wanted than any other device, though they have not escaped criticism.[1] Gas-and-oxygen is generally held to have the advantage over chloroform that uterine contractions are unaffected by its use, but Mr. W. Gilliatt did not except even this drug from his dictum that all anæsthetics inhibit contractions (see p. 201). It seems obvious, from the attention given to this subject of recent years, that the demand for less painful labour will become more and more insistent, and that the public are more interested in the solution of this problem than in any obstetric develop- including even the reduction of maternal m- and morbidity.

VITAL STATISTICS FOR 1932

The Registrar-General has issued a prov- statement of the figures for birth-rate, death- and infant mortality during the year 1932.

—	Birth-rate.	Death-rate.	Infant mortality.
England and Wales..	15·3	12·0	[illegible]
118 county boroughs and great towns including London ..	15·4	11·8	[illegible]
126 smaller towns ..	15·4	10·5	[illegible]
London (administrative county)	14·3	12·3	[illegible]

The smaller towns are those with estimated populations of 25,000–50,000 at the 1931 census. birth- and death-rates for England and Wales relate total population and are calculated on the estimated 1932 population. The remaining rates are calc- on the estimated mid-1931 resident population. and to the total population for births, but to the civil pop- only for deaths.

The Registrar-General remarks that for the for- year in succession the birth-rate is the lowest r- record, being 1·0 per 1000 below that of 19- 1930, and 0·5 below that of 1931. The death is 0 3 per 1000, and the infant mortality-rate per 1000, below that for 1931. The only year a lower rate is 1930. In 1928 the rate was the sa- namely, 65.

Mr. H. J. Simmonds, formerly legal adviser the Board of Education, has been appointed as secretary of the inquiry into the affairs of University of Durham College of Medicine, Newca- which is to be held shortly by Sir Amherst Bigge.

The third International Pædiatric Conference be held in London from July 20th–22nd under presidency of Dr. G. F. Still. The proceedings include general discussions on the Nature of Al- and its Rôle in Diseases of Children, and the Pr- laxis of Milk-borne Diseases. Members who to make communications should inform their national committees, the secretary of the B- committee being Dr. Leonard Findlay, 61, Ha- street, London, W.1.

INDEX TO "THE LANCET." VOL. II., 19

The Index and Title-page to Vol. II., 1932, was completed with the issue of Dec. 31st, is in preparation. A copy will be sent gratis to scribers on receipt of a post-card addressed to Manager of The Lancet, 7, Adam-street, Adel- London, W.C.2. Subscribers who have not alr- indicated their desire to receive Indexes regularly published should do so now.

Stamps for a Contributory Scheme.—The Merseyside Hospitals Council, which collects £10,000 a year from 33,000 contributors, has ad- simplified scheme of collecting the money. The contr- are being supplied with cards similar to national insurance cards, upon which they will affix stamps in value from 1*d.* to 5*d.*, purchasable at the various The stamps will be placed on the cards and cancelled by a date stamp. By this system labour will be sav- book-keeping simplified.

another paper. A subsidiary purpose was to over whether children living in the more densely ulated or overcrowded boroughs in London l to be attacked at earlier ages than children ng in boroughs where housing conditions are better, . this problem is dealt with below. I am greatly ebted to Dr. C. J. Thomas of the London County uncil for suggesting and arranging for this inquiry. he investigation only related to children under- ng medical examination as entrants to elementary ools, where one of the parents was present at the mination. The parent was asked whether the ld had ever had whooping-cough, and the children each age were classified according to whether the ly was affirmative, doubtful, or negative. Out of 38 children aged 3, 4, 5, 6, or 7 in this category mined between April 26th and July 20th, 1932. replies were doubtful in regard to 227. The ubtful cases were therefore omitted entirely and the portion of affirmatives in the total of affirmatives d negatives was taken to represent the proportion all children attacked by whooping-cough up to mean age of the group in question.

Combining all the metropolitan boroughs the result was as shown in Table V.

The irregularity in the steps by which the percentages increase is partly accountable for by the fact that the mean ages of the groups are not necessarily 3½, 4½, &c., but are influenced by the rules as to ages at which children enter school. The group of entrants aged 5 last birthday has doubtless a mean age less than 5½, and the group of entrants aged 4 last birthday has doubtless a mean age greater

to sex, age, and month of the year when whooping-cough began, shown in Table II., indicates that from October to January the ratio of girls to boys, based on 1383 cases, was 1·0073; from February to April, based on 1339 cases, it was 1·2206; and from May to September, based on 1166 cases, it was 1·2337. Stated in another way, the percentages of females were respectively 50·18 ± 0·91, 54·97 ± 0·92, 55·23 ± 0·98, the differences between the first and second, or first and third, being four times their probable errors.

Total	1383	1000	1·0073	1339	1000	1·2206	1166	1000	1·2337	–

The sex ratio in the census population under 10 being 0·9750, it is evident that in the autumn months and January girls under 10 were about 3 per cent. more susceptible to contract whooping-cough than boys, but during the rest of the year girls under 10 showed an excess of about 25 per cent. in susceptibility in comparison with boys. In January, February, and March the ratios were 1·0404, 1·1900, and 1·1734 respectively, the equivalent percentages of females being 50·99 ± 1·58, 54·34 ± 1·60, 53·99 ± 1·45. The month of April gave the highest ratio, 1·3355; in September it was 1·2462, and in October, which gave the lowest ratio, 0·8889. This seasonal difference in sex ratio is only apparent at ages under 7, as shown in Table II. The per mille distributions of ages show that whooping-cough does not tend to attack younger or older children to any significantly different extent in winter and summer.

Separating the Greenwich cases into three groups, (*a*) "primary" cases followed by one or more subsequent cases in the same house starting between four days and three months after; (*b*) "subsequent" cases as above defined; (*c*) cases not included in (*a*) or (*b*), the percentage of females were as shown in Table III.

TABLE III

—	Oct. to Jan.			Feb. to Sept.		
	M.	F.	Per cent. females.	M.	F.	Per cent. females.
(*a*) ..	90	86	48·86 ± 2·54	115	146	55·94 ± 2·08
(*b*) ..	89	88	49·72 ± 2·53	156	185	54·25 ± 1·82
(*c*) ..	510	520	50·49 ± 1·05	854	1049	55·12 ± 0·77

(*a*) Primary. (*b*) Subsequent. (*c*) Other.

This shows that the increased liability of girls during a part of the year was equally evident whether they contracted whooping-cough outside or inside their homes.

Sex- and Age-incidence in Battersea

In Battersea the excessive liability of girls to whooping-cough was much less pronounced. This is shown in Table IV. The ratio of girls to boys in the census population was also higher, and at all ages under 10 in 1921 the sexes were approximately equal in numbers, the ratio being 1·002. There was therefore at ages up to 7 an excess of only 5 per cent. in the liability of girls to whooping-cough, compared with 15 per cent. in Greenwich, but at all ages over 7 combined there was in each borough an excess of about 40 per cent. Amongst the "primary" cases, here defined as those which were followed by another case in the same house after an interval of 4 to 28 days, the sex ratio at ages under 10 was 1·201, which is apparently but not significantly higher than the ratio for other cases. No significant difference was found in the ratios in different epidemic phases. The distribution of primary cases by age in Battersea shows a relative excess of children at ages 4, 5, and 6 above the expected numbers based upon the distribution of all cases under 10 years of age; the actual number at these ages was 403 out of 715, and the expected number 322. The chance of such a distribution of primary cases arising by random sampling is less than one in a million. It is evident that children at these ages are more liable to infect their brothers and sisters than are younger or older children. Thus 14·8 per cent. of the children at ages 4, 5, and 6 were followed by a secondary case after an interval of 4 to 28 days, whereas 9·4 per cent. of children of other ages under 10 were so followed.

When the distributions according to age during different phases of the epidemic cycle are compared with the expected figures, a slight excess of children at ages 3 to 6 and a corresponding deficiency at ages under 3 is noticeable during the rising epidemic phases. There is also a relative excess of babies attacked in the interepidemic periods.

Incidence with Age in Different Parts of London

During the spring and summer terms of 1932 a special inquiry was carried out by the school medical officers of the London County Council to ascertain what proportions of children entering school at ages 3, 4, 5, and 6 had suffered from an attack of whooping-cough. The main purpose of this inquiry was to discover what fraction of the total incidence of whooping-cough at pre-school ages is reported to the health offices in those boroughs where the disease is notifiable, and this aspect of it has been dealt with urally checked by the judge, whose reputation ds no defence here. It looks as though the ler of the girl had himself to thank if the jury unfavourably disposed towards the claim from outset. He had written a disingenuous letter to school authorities on the day after his daughter's ration, attempting to trap them into some nission which would prejudice their defence when al proceedings were initiated.

Noise Nuisance (Infants' School)

Another school was a less successful defendant in High Court last week, Mr. Justice Eve granting injunction against it to a neighbour who complained the din made by some 30 young children in a yground 36 feet by 23. The school prospectus s quoted to show that the teachers interfered little as possible and allowed the little pupils to velop their independence unchecked. The plaintiff's fe said she woke up every morning hoping for a t day because the children would then be kept doors; another witness said she prayed for fine ather because the children made so much noise if pt indoors. Mention was also made of dancing-sses, and of a bonfire on November 5th. The dge thought the dancing was no great matter, d it would really be intolerable, he said, if children uld not celebrate Guy Fawkes' Day with appropriate remony. The question of noise-nuisance is one of ace, time, and volume. The school was situated Fitzjohn's-avenue, Hampstead. There was no gal restriction preventing the existence of a school ere. A properly conducted school does not consti-ite an actionable nuisance. The plaintiff had to ow that the noise was excessive and was not roperly controlled, and that it seriously affected s comfort in his home. If it was no worse than e noise reasonably incidental to the carrying on a school of that kind, the plaintiff must put up with . The judge considered that the playground space as too small and that there were occasions when e teachers had failed to check noisy children. ut, in granting the injunction, the judge said he oped it would not be harshly used. He suggested at an enlargement of the playground space, paration of the elder from the younger children, d better supervision of any excessively noisy child ould probably suffice to keep the school from fringing its duty to its neighbours.

People who desire to take legal proceedings for e nuisance of noise should make methodical notes the annoyance of which they complain—a diary events is often useful. It is common knowledge at successful plaintiffs are often members of the gal profession who not only know their rights, but so know how to marshal and present the evidence support of their claims for protection.

IRELAND

(FROM OUR OWN CORRESPONDENT)

CHANGES IN ADMINISTRATION

Two important changes in administration have cently taken place in regard to health affairs in e Irish Free State. The National Health Insurance ommission has been abolished, and its place is ken by a controller directly responsible to the inister for Local Government and Public Health. he Commission was appointed in 1912, consisting of chairman and three members, of whom one was to be a medical practitioner and one a woman. The original members were Mr. (now Sir) Joseph Glynn, chairman, Mr. (now Sir) Walter Kinnear, Dr. W. J. Maguire, and Mrs. Dickie. Sir Walter Kinnear was transferred to London during the war years, and is now controller of National Health Insurance in England. His place on the Irish Commission was not filled. The other three commissioners remained in office until December 31st last, when the Commission itself was abolished. The medical profession will regret the change both on personal and general grounds. Although the profession and the Commission did not always see eye to eye, the relations between them had for many years been friendly. The presence of a medical man in the body of the Commission ensured that the medical point of view should be recognised there, and Dr. Maguire, who in his early years of office had to contend with many difficulties, had gained for himself the respect and friendship of the medical men who had business with him. It is doubtful whether a lay controller can be as independent as the Commission, but Mr. J. A. McCarron, who has been appointed to the office, has a long experience of the work of the Commission, to which he has been secretary for the past three or four years.

Another important change is the retirement from office of Mr. Edward Francis Stephenson, chief medical officer of the Department of Local Government and Public Health for the past ten years. Before his appointment to this office he had experience as a country dispensary doctor and as Local Government Board inspector. He took up duty at the moment when the establishment of the Irish Free State at once shook traditional methods of administration, and made possible schemes of reform in the public health services long overdue. The infant State was fortunate in having as its chief medical adviser a man well trained in administration and at the same time of progressive mind. The history of Mr. Stephenson's decade of responsibility is the history of a decade of steady and well considered reform in the health services. The county area of administration has been substituted for the poor-law union; the appointment of officers of local authorities has been entrusted to a central commission and freed from the unsavoury environment which formerly surrounded it; county medical officers of health have been appointed in the several counties; the local hospitals have been improved out of recognition; and, finally, the conditions of remuneration and service of the medical officers have been revolutionised. Some of these changes had been begun in earlier years, but their completion has taken place during Mr. Stephenson's term of office, and are largely due to his persistence and influence. His personal relations with the profession have always been of the happiest. Approachable, fair, and upright, he has commanded the respect and liking of his subordinates. With a high ideal of what professional conduct should be, he has insisted on a high standard of service, but he has also defended the members of the medical services against unfair criticism and imposition of every sort. Mr. Stephenson is a Fellow and member of Council of the Royal College of Surgeons in Ireland; a few months ago he was elected an honorary Fellow of the Royal College of Physicians of Ireland in recognition of his services to public health. It is understood that his place in the Department of Local Government and Public Health is to be taken by Mr. Robert Percy McDonnell, F.R.C.S.I.

NOTES FROM INDIA

(FROM OUR OWN CORRESPONDENT)

THE ALL-INDIA INSTITUTE OF HYGIENE

AN event of some importance in the history of medicine in India was the public opening of the All-India Institute of Hygiene and Public Health in Calcutta during Christmas week. The ceremony was to have been performed by the Viceroy, and many of those who were assembled in the fine reception hall, which is a feature of the new building, were surprised to see Sir John Anderson, the Governor of Bengal, arrive in the place of Lord Willingdon, who was indisposed. A gift from the Rockefeller Foundation, the institute was completed a year ago, and it was hoped that the six sections which the Government of India had promised to maintain would be opened at the beginning of last financial year, but nothing happened. We understood that it was decided to open the institute with four sections instead of six as promised, but even this remained as a paper decision, and the sanction for the appointment of the director and his assistant only arrived at the last moment. We all looked forward to an announcement by the Viceroy, or his deputy, that the institute was at least to commence work with its four sections this year, but no announcement was made. However, we understand that definite permission has now been granted to advertise the appointments, and it is hoped that within a few months the institute will be more than a mere building ; the four sections that are to be opened are public health administration, vital statistics, and epidemiology ; malariology ; rural hygiene ; and biochemistry and nutrition. The institute is to work in coöperation with the School of Tropical Medicine where hitherto the D.P.H. training has been carried out, and where some of the class-work will still be done.

PROGRESS OF RESEARCH

The Tenth All-India Research Workers' Conference was held in Calcutta again this year during the first week in December. The cloud of financial stringency still overshadowed the proceedings, but otherwise the conference was a distinct success. One of the noticeable features was the large attendance of provincial directors of public health. The exceptions were Bombay and Assam, which were represented by the director of the Haffkine Institute, and by the inspector-general of civil hospitals and the director of the Shillong Pasteur Institute, respectively. The Army sent two representatives. Altogether there were over 60 delegates. Major-General Sir J. W. D. Megaw, I.M.S., was the chairman. It was General Megaw who originally suggested, a little over ten years ago, that this conference should be held in order to obtain the opinion of research workers in different parts of India as to the best policy to adopt regarding the expenditure of the income of the Indian Research Fund Association which had been curtailed by the suspension of the annual grant. The grant was in time restored, but has again been cut, and, in order to save the trained personnel of the department from being disbanded, the research programme this year will have to be financed almost entirely out of capital. The future of research in India is thus not on a very sure foundation. However, it is the only thing to be done ; this capital was accumulated for a specific purpose, the building of a central research institute, a project which has now been practically abandoned, and it will always remain a source of grievance to the finance department and an excuse for withholding the research grant.

Colonel R. McCarrison made an impassioned appeal for the extension of research on the subject of nutrition and the establishment of a nutritional institute. We all heartily agreed with Col. McCarrison, but he almost defeated his own ends, because when the spell of his speech had passed off we began to wonder what had been the substance of his suggestions. However, his resolution on the subject was adopted unanimously by the conference.

The cholera research policy came in for some criticism ; there is a feeling that too much attention is paid to the subject of bacteriophage—undoubtedly an important aspect of the cholera problem, but rather a special aspect. Many delegates were disinclined to accept bacteriophage, as a curative and prophylactic agent, at the valuation of its enthusiastic supporters. There is no doubt that India, as a whole, is passing through a phase of very low cholera epidemciity, and the sceptics would like to reserve their judgment as to the prophylactic value of bacteriophage until there is an epidemic year. On the other hand there is little doubt that India is ahead of many other countries in bacteriophage investigations.

The Government of India's quinine policy was again discussed. The government have got themselves so completely tied up in their own red tape that they can do nothing. They have accumulated a stock of over 400,000 pounds of quinine. In these hard times they would much prefer the money this represents, but rules and regulations appear to stop them selling it at a price which anyone can afford to pay for it. So there it stays. General Megaw has a scheme for getting this quinine to the people at a reasonable price, and after years of struggling with the various departments he is now in a position to say that the scheme has made some progress and *may* be brought into operation within the year. We cannot help admiring his persistence and optimism.

The conferment of a K.C.I.E. on Major-General Megaw, which was announced in the New Year's honours list, will be very popular amongst all sections of the medical community in India. First as a clinician, then as a research worker, and finally as an administrator, Sir John has made for himself three separate reputations, each of high order.

BERLIN

(FROM OUR OWN CORRESPONDENT)

HEART DISEASE AMONG ENGINE-DRIVERS

Dr. Munk and Dr. Spiller, of the Martin Luther Hospital in Berlin, find that, according to figures supplied by the Engine-Drivers' Union, 24 drivers have, within one and a half years, suddenly died while on duty. Of those in active employment 130 died from sudden stoppage of the heart and 120 from cardiac diseases. The total represents 36 per cent. of all the causes of death in this occupation. In Germany, as a whole, only 16 per cent. of the male population over 20 years die annually from cardiac diseases, and the great number of deaths from heart diseases among engine-drivers is the more remarkable, as only men of apparently perfect health are appointed by the railways. The number of retired engine-drivers who suffer from cardiac disorders is also very great, and Munk and

Spiller have formed the opinion the cases must be regarded as occupational in origin. At the request of the union they examined 100 members suffering from cardiac troubles. These all complained of heart attacks with dyspnœa, the degree of the pain varying from slight pain to the typical symptoms of angina pectoris. The attacks were produced by strain and nervous excitement, and occurred less frequently during than after work, sometimes at night. In only 13 cases was valvular disease detected, and in 8 cases enlargement. Hypertony was rare. The electrocardiogram did not in the majority of cases give a sufficiently reliable result to decide whether an alteration of the myocardium or only a functional trouble was present. This question is very important for the medical officers of the railways, who have to decide whether a man may continue his service; whether, in order to recover, he should be sent to a sanatorium for a certain time; or whether he should be discharged. All the men examined stated that the great watchfulness and the feeling of responsibility which the work entails are a constant strain on their nervous systems, and that in many cases this strain has been increased by accidents. Some thought that the irregular hours of service, especially the alternation of day and night work, kept them from sleeping well. The great heat in the engine-driver's box is also mentioned as a possible cause. Some complained that they had too little bodily exercise, and thus suffered from adiposity; it is characteristic of this trade that an engine-stoker, who as such must work very hard, grows fat as soon as he is promoted to be an engine-driver, where he has to stand or sit quietly in his box. The results of the investigation show that mental strain is mainly responsible for the cardiac trouble, and that other factors, such as tobacco or spirits, have little or no effect.

OBSERVATIONS ON MEDICAL EDUCATION

Dr. Morawetz, the well-known professor of clinical medicine at Leipzig University, lately discussed some questions concerning medical training. He said that the principal difference between medical education in Germany and abroad is that in Germany theoretical study prevails, whilst in other countries the student comes in contact with the patient from the beginning. The average German student knows more than the average foreign student, while the latter has more practical experience. Generally speaking, the results in Germany are not worse than abroad—a fact also admitted by foreign experts. Prof. Morawetz does not consider it advisable to hold courses in sick nursing, as was suggested, because, owing to the great number of students, such courses would soon become mere lectures. It would be better to allow students to obtain practical experience by working in hospitals during the university vacations. The "numerus clausus"—i.e., a limited entry of students—is deprecated by Prof. Morawetz, as he thinks this might lead to much unfairness. There would be no guarantee that only the best pupils were admitted to the university, and it is known that many good medical men were by no means brilliant at school. Prof. Morawetz strongly opposes the increase of subjects for examination, for he thinks that the most important subjects—which for the medical man are internal medicine, surgery, and obstetrics—have already fallen somewhat into the background. It would indeed be better for some subjects, such as pathological physiology, social hygiene, and insurance medicine, to disappear from the examination. An extension of the curriculum would only lead to an increase of theoretical knowledge. The new regulation that no medical man is to be admitted to club practice without having been an assistant in a hospital is upheld by Prof. Morawetz because it means an increase of medical efficiency, though it means the student must wait rather a long time before he may enter practice.

CORPUS LUTEUM EXTRACT IN HABITUAL ABORTION

Dr. Wolfsohn, writing to the *Medizinische Welt* (1932, vi., 1616), reports that he has had good results in cases of habitual abortion by the administration of a corpus luteum extract called luteogan. This is an oily solution containing one rabbit unit per cubic centimetre, and in cases of bleeding during the early weeks of pregnancy it is given by intramuscular injection daily or every second day. The usual treatment by rest in bed and tinct. opii is of course given as well. Of ten cases treated seven went to term. In one of the unsuccessful cases there was a myoma, and in one a hydatiform mole, while in the third there was a history of prolonged amenorrhœa which suggested some form of endocrine disturbance other than deficiency of corpus luteum. In cases where in previous pregnancies there was bleeding at the time of the expected periods, luteogan treatment was continued at such times during the first few months. In the other cases it was not required after the subsidence of the hæmorrhage. Wolfsohn comes to the conclusion that this remedy should be tried in cases of early habitual abortion for which there is no apparent cause.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

Surg. Lt. G. Rorison to be Surg. Lt.-Comdr.

H. L. Cleave to be Surg. Lt.

The following appts. are notified:—Surg. Comdrs.: A. W. McRorie, to *Ganges;* G. D. Macintosh to *Victory*, for R.N.B.; and W. F. Beattie to *Pembroke*, for R.M. Infirmary, Chatham.

ROYAL NAVAL VOLUNTEER RESERVE

Surg. Sub-Lt. G. H. C. R. Critien and Proby. Surg. Lt. W. Gough to be Surg. Lts.

Proby. Surg. Sub-Lieut. K. W. Martin to be Surg. Sub-Lt.

The following appt. has been made: Surg. Lt. W. M. MacGregor to *Victory*, for R.N.B.

ROYAL ARMY MEDICAL CORPS

Lt. W. J. Officer to be Capt.

TERRITORIAL FORCE

Maj. G. Young resigns his commn. and retains his rank, with permission to wear the prescribed uniform.

B. F. Longbotham (late Cadet Lce.-Corpl., Cambridge Univ. Contgt., Sen. Div., O.T.C.) to be Lt.

ROYAL AIR FORCE RESERVE

Flight Lt. E. A. Aslett is transferred from Class D (ii) to Class D (i).

INDIAN MEDICAL SERVICE

Lt. D. J. Young to be Capt. (prov.).

The undermentioned officers relinquish their temp. commns.: Capts. D. C. Datta and M. N. Rajan.

Mr. J. Currie, M.D. Lond., has been appointed Admiralty Surgeon and Agent for Anderton, Plymouth; and Mr. A. P. McEldowney, L.R.C.P. Lond., M.R.C.S., has been appointed Admiralty Surgeon and Agent for the London District, No. 11—namely, Barnes, Mortlake, and Putney.

SOCIETY OF PUBLIC ANALYSTS.—A meeting of this society will be held at the house of the Royal Society of Medicine, 1, Wimpole-street, London, W., at 8 P.M., on Wednesday, Feb. 1st. There will be a discussion, in conjunction with the food group of the Society of Chemical Industry, on the Changes taking place during the Storage of Fruits.

THE DOCTOR'S DAY

"Come, tell me how you live," I cried,
"And what it is you do!"

XII.—NEAR THE WEST AFRICAN COAST

THE chink of teacups on the tray put down just outside the mosquito house woke me, and I heard the sound of the steward's naked feet as he passed through the dressing-room to his daily work. It was 6.30 A.M. The sun was beginning to show bright points of light in the eastern sky, the cocks with their consorts were calling for their breakfast. The parrots in their commodious house downstairs were going through their vocabulary, wishing all who were within call "good morning," and almost in the same breath remarking "you old rascal." The baby leopards in their quarters at the back were squawking for the steward to come and fill their bottles with warm milk, and the usual morning noises proceeded from the compound. Dan Seriki, wagging his tail, came to the door of the mosquito house for his morning biscuit; he had earned his name ("son of a chief") on an occasion when he had been able to find a guinea-fowl which had fallen to my gun, after three boys had searched in vain for nearly ten minutes. Dan had, they said, "sense past three black men."

DISPENSARY ONE

By 7 o'clock I was downstairs and going to the garage for the car in which to proceed to the hospital and dispensary, about one and a half miles away. On my arrival at the hospital compound which encloses two main blocks—one the hospital with 16 beds, the other the administrative building consisting of a large waiting hall with open sides, consulting-room, dressing-room, dispensary, and office—I found a motley crowd of from 70 to 80 waiting for me, of all ages and of both sexes. They were admitted to the consulting-room in order, one by one, by my interpreter, who introduced them to me and gave me details of their troubles. Many of them were for daily dressings, and they were soon passed on into the adjoining room where they were attended to by several native dressers. These youths, recommended to me by the king of the town, I had been able to train to do simple dressings; and indeed they could put on fomentations and bandage as well as many who have received much better education.

The new cases were generally taken last to save time. As each patient came into the room the symptoms were related and I was able to follow most of what was said; but the language was a difficult one, and I felt on surer ground when I had an efficient translation. In passing, I may say I once asked my boy at dinner to bring the soup and he went at once to the pantry and fetched a carving-knife; alas I had used the wrong intonation, the words being spelt alike. At first I was perplexed because most of the patients said they were troubled by a "worm," and I began to think of ascaris or oxyuris, and sometimes tænia, but I soon found that to the native mind all pain was caused by a "worm," and the position in the body mattered not at all. The difficulty was increased by the fact that to be in the presence of the *Dokita*, as I was called, was causing a certain amount of alarm, but in time as my interpreter got to know the question which I asked as a routine I was able to get to the bottom of the matter. A large number of the patients came with surgical conditions. The natives abhor a deformity, and before the advent of European surgery were bound to suffer without relief; when they found that lipomas could be removed, or inguinal hernia cured, they began to take courage and come for treatment. As one was operated on the news spread. I removed from the back of a woman a lipoma weighing 20 lb.; on account of this she had been turned out of her home; she walked back 100 miles to show her cure, and in a week I had three similar cases from her village. They walked the whole way, carrying food and sleeping-mat.

But to return to my patients. Here is a mother carrying astride her hip a bonny boy with eyes like sloes, soft and velvety skin. He does not mind the strange surroundings and plays while his mother holds a long conversation with the interpreter. I wait patiently until the whole tale is told, for the African has a wonderful memory and will hear the whole story before he commences to interpret. A great calamity has befallen her. At 8 months old her boy has cut his two upper incisors before the lower ones, and she has come to see what the "white man" can do to help her. If a baby cuts the upper teeth first he will grow up to be a giant, and will turn every one out of the compound; even his own father and mother will not be treated differently from strangers. Surely the white man has some medicine which will prevent these troubles. I tell her that in my country it does not matter which teeth the baby cuts first; it is a red-letter day, friends come to congratulate the parents and nothing happens to the baby. I talk a long time and when I thought she seemed satisfied she broke out with a request that would I remove the offending incisors and then no evil could happen. I refused, and she went away sorrowful.

The next is a man with a foreign body in his conjunctival sac. It went in yesterday, and his friends had done all they could and failed. I inquired what had been tried. One man had been told off to hold up the top lid, a second to depress the lower, a third had stood in front of the patient and, filling his lungs to the utmost, had forcibly expired into the opened eye. When I used the usual methods, and showed him the offending body, his idea of the medicine of the white man was very high. The next had a fish-bone in his throat. He had tried without success the native method of treatment, which consisted in giving the sufferer a smart blow on the top of the head with the hope that the tonsil would recede and leave the bone free on the surface; no care being taken to avoid a possible dislocation of the vertebræ. A pair of forceps and a tongue depressor sent the man to join the group outside for a gossip before returning home. Then came one or two who wished to have teeth extracted, unheard of before the white man came; in most cases there was no trouble, as pyorrhœa had been allowed to get the upper hand.

The examination of recruits for police, of any school-boys who might be ill, and attendance on sick prisoners, which consisted mostly of minor injuries, kept me occupied until 9 o'clock, when I went home to breakfast.

DISPENSARY TWO

At 10 o'clock, taking my interpreter, I went to the town where the king had built a second dispensary to accommodate those unable for any reason to get to the other. This one was about two miles from the first. The native population of the town is nearly 80,000, the province being about 17,000 square miles in extent. My hospital is the only one in the province, my nearest colleague being 60 miles away to the south or 150 miles to the north. At the dispensary I found a number of children waiting in the verandah. They had small cuts or ulcers and were attended to by native dressers. There were a number of women with babies on their backs, and at a distance a crowd of men in the picturesque dress of the Haussas. They were there to see what was going to happen to the children, as they had been told by the *Registrar* to bring their wives and children to the *Dokita* and could not understand why. Every birth is reported to the man appointed by the king, who keeps a record of them for me. Month by month the six-months-old babies attend at the dispensary, when I examine them for general fitness, splenic index, and at times take smears to examine for malarial parasites. Then I vaccinate them. At first there was some dismay at the white man's medicine, but when it was explained that this would prevent small-pox there was not a murmur. All know the dire results of small-pox; blind and deaf children are seen on every hand. This elementary effort at infant welfare has been going on for several years, and the infant mortality-rate has fallen from 300–400 to nearer 200 per 1000 births.

By this time it is nearly noon, and as the sun is very hot I return to the hospital to do my morning round there. Most of the patients are convalescent. Several of them have had fractures, which are getting more numerous owing to the number of motor lorries running to the villages around. These lorries were licensed to carry 20 persons besides the driver and his apprentice, but more often than not there are nearer 30 crowded in, and a passenger may fall out or get under the wheels. One or two patients were recovering after radical cure of hernia or hydrocele. I was soon free to retire to the office where papers are typed by my dispenser, ready for the weekly mail to headquarters. One train up and one down to the coast complete the weekly service except when the mail-boat arrives, and once a fortnight the boat-train passes carrying our letters and newspapers, and there is a feverish rush for the post office.

VISIT TO AN OUTLYING STATION

As it was Saturday, and the day on which I usually visited the dispensaries in the district and did general inspection, I gave instructions for the labourers to proceed to my house and carry my loads to the station to catch the local train. My steward had already packed bed, bath, with all the pots and pans which he would need for my meals, chair and table, as it would be necessary for me to spend the night at a rest house. These are houses built by the natives themselves of mud, roofed with grass, with no doors or windows but with mud partitions to allow of two apartments. The floor was concrete, and in each village the chief deputed a man to brush it and have wood and water ready for any officials who might be coming to the village. Lunch having been enjoyed, and a rest necessary on account of the great heat, sometimes 100° F. in the shade, I started. The loads were sent on by train, while with the dog and my gun, in case we saw a guinea-fowl or partridge on the way, and my steward and interpreter behind, at about 3 P.M, I set out by car to do the 63 miles to my destination.

The road was quite good, although in places very hilly; we passed several villages and were saluted by the chiefs and headmen, of whom I made inquiries as to the presence of infectious disease and the like. When about half-way the sky was overcast by a swarm of locusts which came in through the windscreen and windows until both the dog and myself were obliged to protect ourselves. However, the swarm was not a large one, but farther on my journey I saw evidences everywhere of the destruction they had caused. In the maize farms not an inch of leaf remained; and where a day before there had been good crops, now there was nothing but a forest of stalks.

About 5.30 P.M. I arrived at my destination, and as the road to the rest house led past the chief's house it was not long before a procession was seen wending its way to salute me. The old chief led the way, and in the native fashion welcomed me to the town. I made inquiries as to his health and that of his family, his farms, the damage done by the locusts; then a small boy was beckoned forward, carrying a calabash which contained some eggs, and in the other hand a fowl. This was the offering from the chief, and my steward, knowing the custom, came to me for a threepenny-bit which was the perquisite of the small boy, the goods themselves being paid for when I settled up next day for the wood and water necessary for cooking and bath. The chief then retired, having told me that several patients wished to consult me, but as it was late they would come in the morning. Soon after a procession of women came with pots of water on their heads and poured it into large pots holding about 20 gallons which were permanent fixtures at the rest house. A man brought enough wood to supply the needs of the fire until the morning, and the steward and interpreter busied themselves in getting up my bed before the darkness set in.

There are outbuildings at each rest house for the kitchen, and sleeping-quarters for the staff, whose night requirements are a grass mat to lie on, and a cloth like a sheet in which to envelop themselves. After a hot bath and dinner I sat outside where I intended to sleep and, lighting my petrol lamp, set myself to enjoy a book; but soon the mosquitoes got so troublesome that I found it better to get inside my net and read there. I had put down a canvas bag for the dog, and I found I was more inclined to sleep than read. And so the day ended.

PANEL AND CONTRACT PRACTICE

"Personal Service"

THE extent to which a panel practitioner is bound to give treatment himself depends on the organisation of his practice. If he is single-handed without a partner he is not only personally responsible for providing adequate medical treatment for his insurance patients, but is also required to give the actual treatment himself. Obviously he could not be allowed to undertake to attend Mr. A when ill and then to send him on to someone else who could charge him for medical service. But regulations governing partnerships definitely provide that the treatment need not be given personally, though the insured persons' rights are protected by certain conditions. For example, continuity of treatment must be ensured whether the practitioner with whom the patient is insured, his partner, or his assistant is attending the case; further, the insured person can demand to be treated by the principal rather than by the assistant, but he has no such right in respect of a partner. Even the demand to be treated by the principal rather than by an assistant will not succeed if the principal is prevented from attending or is unwilling to attend by urgency of other professional duties, temporary absence from home, or other reasonable cause. In the case of partners then, personal service is not required, though when it comes to assistants the insured person has a stronger claim. Here the insurance committee endeavours to exert some pressure, for to employ a *permanent* assistant to do work under the panel requires the consent of the insurance committee. If such an assistant is appointed, and a scrutiny of prescriptions by the insurance committee indicates that the principal is not doing what they think is his fair share of the work they will try to withhold permission to employ an assistant. Refusal of this permission requires the acquiescence of the panel committee.

In the appeal case reported in our columns last week (p. 159), in which an elderly doctor won his appeal against the London insurance committee, the question of personal service was the main principle involved. It must not be forgotten that in connexion with these cases whoever is actually treating a panel patient, the principal is entirely responsible for all acts and omissions of the medical attendant, so that he does not escape blame if anything goes wrong.

The attitude of insurance committee members is curious when it is remembered that they are concerned with the interests of insured persons. In these days panel patients may be expected to complain if they do not receive the treatment they expect, or think themselves entitled to. Moreover the days when insurance practitioners were scarce have gone by. and most practitioners find competition increasing. Unless therefore an assistant in a practice is doing his work properly the principal is not likely to retain his services. The panel committees' point of view in these cases is probably the avoidance of "farming out" or the exploiting of one doctor by another. In the case in question there was no farming out at all. Almost unanimously the panel committee passed a resolution that he should be allowed an assistant, the grounds for this decision being that it was in the interest of insured persons themselves. Here was a practice admirably run by an assistant who was popular with the patients and well known to them. He refused to be a partner, preferring his position of assistant. If the opinion of the insurance committee had been upheld the fetish of "personal service" would have resulted in inconvenience to insured patients, with whom the assistant was popular, and hardship to the principal, to the widow, and children of the doctor whose practice he had taken over.

The question of permission by an insurance committee to employ an assistant arises only when this is to be a permanent arrangement. So far as we know no definition has been laid down what is a temporary arrangement. Possibly it would be held to apply to a whole-time assistant employed for more than a reasonable time required to tide over some emergency and might still count as a temporary assistant. But an assistant who became necessary to the principal's practice by reason of the numbers of his panel being higher than that allowed by regulations for a single-handed practitioner would certainly not rank as a temporary assistant. It is doubtful if permission is required for the employment of a part-time assistant.

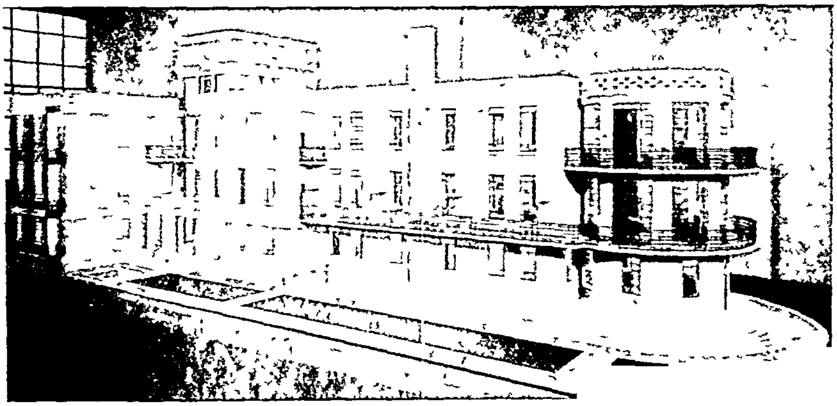
Permanent assistants are usually required to have their names placed on the panel list for the area, but insurance committees are disinclined to encourage such assistants to accept names of patients on their own lists, owing to the amount of clerical work involved when they move on to some other practice or area. If the names are all kept on the principal's list, no such clerical work becomes necessary when a change of assistant is made. Insurance committees cannot of course prevent an assistant from accepting patients for his own list, but they generally suggest to the principal that the acceptances should be for the principal. When subsequently prescriptions are scrutinised to discover the work being done by principal and assistant respectively, the percentages are calculated on the total numbers of the practice. This method of calculation makes it appear that the principal is doing less work than he actually is doing; for in many cases insured persons have joined the panel of this particular practice because they like the assistant and are really therefore his patients though counted for insurance purposes as belonging to the principal. There is probably very little difference from a regulation point of view between a deputy and a temporary assistant, for in either case signatures have to be on behalf of the principal—e.g., A, B, C, for Drs. X, Y, Z.

Deputising

The question of deputising was one of the deciding factors in the other appeal reported last week, also lost by the insurance committee. Here the work required for many of the insured persons in a London hospital was done by a non-panel medical man, but it was denied that he was the deputy of the superintendent of the hospital who was their insurance practitioner on the panel. Here the insurance committee held that a panel doctor was responsible for the certification of insured persons who never consulted him, but who of their own free will received treatment from another doctor, non-panel, and not even under the orders of the superintendent of the hospital where treatment was being given. Now in ordinary general practice many insured persons obtain treatment and certificates from other doctors, panel or non-panel, without the knowledge of their own insurance practitioner. How could he possibly be held to be responsible for such certification? In this case as in the other, the insurance committee, obsessed by "personal service" fetish, were discontented with arrangements under which the insured persons were receiving first-class treatment without cost to the drug fund, and because the certificate given to the insured person did not comply with the National Health certification rules. The obvious remedy for the societies concerned was to refuse to pay sick pay on such certificates. These certificates are always handed to the insured person and are his property. If they are not in order it is the patient's business to have them altered to conform to the rules of his society. The real irregularity was that the certificate from a non-panel doctor did not comply with the certification rules. The clerk of the committee tried to make a subtle distinction between breaking regulations and failing to comply with the regulations, but the legal authorities would not accept this, and the fact that the appeal of the medical superintendent of the hospital was allowed will give general satisfaction.

A PRESENTATION MOTOR AMBULANCE. — The employees' friendly society of the London General Omnibus Co. last week presented to the Manor House Hospital, Golders Green, a 20 h.p. Austin ambulance which cost approximately £800. During the past ten years the omnibus men have contributed over £61,000 to the hospital, and made grants exceeding £5000 in addition. The new ambulance replaces one given in 1926.

HEREFORDSHIRE GENERAL HOSPITAL MEDICAL STAFF.—By the rules of this Hereford hospital there are three honorary physicians and three honorary surgeons. At a recent meeting of the board of management a resolution was passed by 38 votes to 16 that the honorary medical staff should consist of such physicians and surgeons as the board should appoint. When, at the next meeting, the resolution came up for confirmation it was defeated by a majority of 26 to 19. The reasons advanced in favour of the change were that the work had greatly increased owing to the growth in the number of patients, and that in the last few years the nursing staff had gone up from 24 to 56. In opposing the confirmation on behalf of the honorary medical staff, Dr. F. O. T. Strange pointed out that in the last ten years the number of major operations had increased only from 743 to 818 in a year. He argued that it was necessary for the maintenance of his skill and knowledge that an honorary surgeon at a hospital should perform at least 300 or 400 major operations per annum, and produced figures from other hospitals in support of his contention. The board of management had been circularised against the confirmation of the resolution by the entire honorary staff of the hospital.

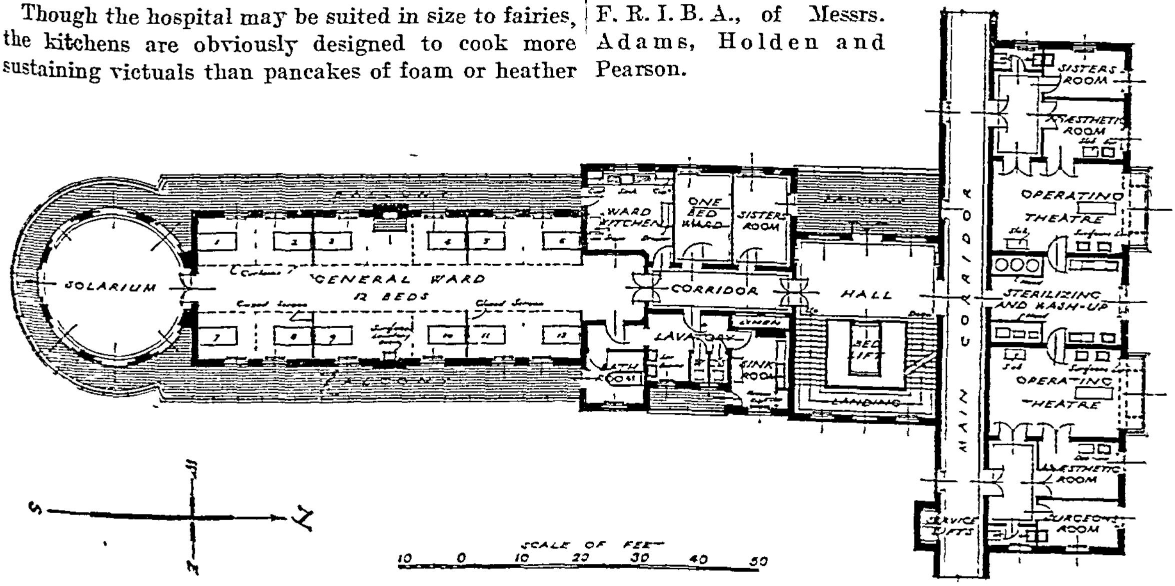


THE MINIATURE HOSPITAL

IN the three weeks of its exhibition at the Building Centre, 158, New Bond-street, the King's Fund model hospital has had more public attention than any other hospital in London. It interests the simple because it is a doll's house, the clever because it is ingenious, and the expert because it embodies the newest ideas of other experts. Those unfamiliar with the inner workings of a hospital can study it with an ease and detachment which is impossible in an establishment where the patients are of full size, the work non-stop, and visitors less welcome. The accompanying plan illustrates the information already given in THE LANCET (Jan. 14th, p. 95). It will be seen that the architects have once more adopted the arrangement by which the beds are placed parallel to the walls, and are partly separated from one another by glazed screens. The advantages claimed for this are that the patient has greater privacy, that he is no longer forced to face the light, and that the radiator which is usually placed under the window is near his feet instead of his head.

Though the hospital may be suited in size to fairies, the kitchens are obviously designed to cook more sustaining victuals than pancakes of foam or heather ale; the visitor hears talk of such technical things as steam-jacketed boiling pans with draw-off cocks. There are roasting and baking ovens, a grill, and in the centre of the kitchen is a gas-heated hot-plate. The kitchen can provide for 300 patients and staff, and everything is designed to ensure cleanliness. The lift has a speed of 90 inches a minute, and the liftman seems to find no difficulty in operating it.

The list of firms who have collaborated in the construction and equipment of the model is impressive. Material has been drawn from far and wide; if London provided the bodywork of the motor ambulance, the chassis had to come from Birmingham. No fewer than a dozen kinds of wood have been used in the different parts of the buildings and fittings. The task of building the hospital was made even more difficult by the fact that it had to be strong and compact to stand the long journeys it will make; for people all over the country can look forward to seeing the hospital when it leaves Bond-street. There, however, it remains until Feb. 4th; and there it should be seen. The architect is Mr. Lionel Pearson, F.R.I.B.A., of Messrs. Adams, Holden and Pearson.



CORRESPONDENCE

INFLUENZA

To the Editor of THE LANCET

SIR,—In view of the widespread desire for information of practical value concerning the ætiology of influenza it is perhaps a little rash to broach this matter at all. Nevertheless, I do venture to ask whether your leading article in THE LANCET of Jan. 21st, p. 149, admirable though it be as a summary of recent work on colds, is not too pessimistic on the subject of influenza?

Consider, for instance, the illuminating experiments made in Japan on 52 doctors and nurses who volunteered for this purpose at the time of the pandemic of 1918, and reported in THE LANCET (1919 i., 971) by Yamanouchi, Sakahami, and Iwashima. The sputa of 43 cases of influenza were emulsified in Ringer's fluid. This emulsion was injected into the nose and throat of 12 healthy persons, and the Berkefeld filtrate into 12 more. The results were very striking: among the subjects were 6 who had recently had influenza, and these escaped; the remaining 18 all developed influenza after an incubation period of two to three days. A filtrate of the blood of influenza cases was now injected into the nose and throat of six more healthy persons: the results were precisely the same as in the previous experiments. They next tried the subcutaneous route: four healthy persons received filtered sputum, and four filtered blood; all, with the exception of one who had previously had the disease, developed influenza after an incubation period of two to three days. On the other hand, a pure culture of Pfeiffer's bacillus and a mixture of Pfeiffer with pneumococci, streptococci, taphylococci, and diplococci from the sputum of influenza patients was sprayed into the nose and throat of 14 healthy persons, but no symptoms and no illness followed. Yamanouchi and his colleagues concluded that influenza is due to a filtrable virus which is present in the sputum and blood of influenza patients, and can infect either by implantation on to the mucous membrane, or by inoculation, and that Pfeiffer's bacillus and other bacteria found in the sputum are not the cause of influenza. They point out that all the subjects who had influenza, or who received the sputum emulsion or its filtrate became immune.

These human experiments could be repeated, if necessary, provided that a sufficient sum of money was set aside for the necessary accommodation, equipment, and, possibly, compensation. But it would be desirable first of all to see if the main points could be worked out on the lower apes or other animals, and here the following experience may be of interest. When a sharp outbreak of influenza occurred among the nursing staff at St. Bartholomew's in January, 1922, and material could readily be obtained during the first 24 hours of the attack, a number of nurses who were warded in the acute stage were asked to blow their noses into small pads of cotton-wool. These pads were at once dropped into a flask containing about 200 c.cm. of normal saline, and were shaken. The fluid was then taken to the laboratory, passed through an ordinary Berkefeld filter, and one half of the filtrate was heated to 56° C. for 30 minutes. A pair of guinea-pigs, rabbits, and rhesus monkeys were now injected intracerebrally with the filtrate, one of each pair receiving the raw material, the other the heated. The result was as follows: There was no difference in the effect on the two guinea-pigs or the two rabbits, all of which escaped disease. The day after inoculation, also, there was no difference between the two monkeys. On the next day, however, whereas one monkey was well, the other appeared to be having a typical attack of influenza with other symptoms suggestive of encephalitis. It remained in that state for five days and then recovered. The affected monkey was the one that had received the unheated filtrate: the other escaped illness.

This is, of course, merely a single experiment, but it could easily be repeated if the opportunity occurred of obtaining material at the onset of an outbreak in a hospital with an adequately equipped bacteriological department, where rhesus monkeys happened to be available, as in this particular instance. In view of the steady progress that is being made in our knowledge of the viruses, I would submit that the outlook as regards influenza is one of confident hope rather than anything else. At its worst, the position is far better than the state of affairs as regards small-pox before the work of Edward Jenner.

I am, Sir, yours faithfully,

London, W.C., Jan. 21st, 1933. M. H. GORDON.

EFFICIENT MEDICAL SERVICE

To the Editor of THE LANCET

SIR,—The subject of your leading article of Jan. 7th concerns a large part of the population. It affects not only those included in the National Insurance scheme but many persons with small incomes, and also those who are earning what may be considered a comfortable salary but have no reserve to fall back upon in case of incapacity from illness. An increasing number of such persons are compelled to seek hospital treatment. They desire to have specialised treatment but cannot afford the cost.

Specialised treatment is often necessary to remove localised disease; it is also true that when disease is generalised and severe, if anything can be done at all beyond keeping up the patient's strength, specially skilled treatment is needed. People when they fall sick and do not soon recover often believe that their own doctor has not the skill necessary to diagnose their complaints; or if he has, that he has not adequate means of treatment at his disposal. In cases which require special methods of illumination to see the affected organ the public are probably right. No practitioner who sees only occasional cases has the opportunity of becoming so adept in manipulating the instruments and so skilled in recognising what is visible as the doctor who confines himself to the sort of practice requiring them.

With regard to the second assumption—namely, that he has not as a rule adequate means of treatment at his disposal—the public is again often right. If we leave out the large group of temporary ailments—coughs, colds, indigestion, &c.—which recover quickly with medicine and directions, there are a great number of cases of physical disability which might be temporary but may become permanent. Such are disability of the feet, as a result of temporary ill-health or of a period of malnutrition, weakness of the abdominal walls, and displacement of the abdominal organs following childbirth or an acute illness and imperfect convalescence; and rheumatic changes, neuritis, or neuroses following an-injury or a sprain. Rarely has the practitioner the equipment in his surgery to deal with these. Being short of apparatus he lacks the knowledge derived from experience in its use. For such cases specialised treatment is advised and sought. This may be obtained at the out-patient department of hospitals or at special clinics. How are such cases to be treated without a great expenditure of time on the patient's part? The poor especially have to pay heavily in discomfort, loss of work, and in suffering as well as in time when they are affected. Four solutions can be suggested.

1. Enlarge hospital out-patient departments, increase the staff, and organise the attendances just as you would in a business or in a factory. Attach out-patient departments to what were once the poor-law infirmaries but are now well-equipped hospitals.

2. Extend municipal clinics. Many municipalities provide an excellent school medical service. When the boys and girls now at school grow up will they not ask, Why not continue it for us?

3. Attempt to induce some wealthy approved or insurance society to set up clinics for the treatment of those who insure with them. An appeal might be made to the new rich to assist the new poor in setting up such clinics.

4. The establishment of "medical houses" owned by medical practitioners. A start might be made by a number of medical men who could afford it putting down in common enough money to buy a house, equip it with apparatus for physical treatment, engage sufficient nursing help, and also a clerical staff to arrange appointments and keep records and the books. The spirit of exclusiveness should be absent from a medical house; any medical man who decided to pay a share either in starting the house or in paying rent for his room would be able to see all his patients there and treat them there as well. The attempt should be made in a small way at first till the scheme was tested, its strong points ascertained, and its weak points ascertained and remedied. As the doctors would own the medical house and be responsible for its expenses the incentive to effort to make it a success and a paying proposition would be strong. The incentive to effort on the patient's part, if he is not worn out by long and ineffective treatment carried out in an unbusinesslike manner, would also be strong. He wants to get well. Some patients would prefer to pay for treatment when they needed it; others would prefer to enter into some insurance scheme so as to be assured of treatment if and when they needed it. The medical house should be run on a cash basis. This would be easier than medical practice is at present. There would be an office at which payment would be made for any physical treatment given. The pooling of overhead charges would result in a reduction of expenses to the medical men. This would enable them to concentrate on developing methods of treatment. The result of establishing such a medical house would be that the standard of everyday medical treatment would be greatly raised. Moreover, the public would have their confidence increased.

It would follow that approved specialists in radiology, pathology, and other recognised branches would attend at stated intervals. They would pay their share in the expenses of the medical house and receive payment for their work. The problem of the out-patient department of our hospitals would in course of time be solved, to the great benefit of the hospital, the patients, and the doctors. The backbone of the profession, the general practitioner, would gain in skill, work, and reward.

The fourth alternative is the one which I prefer.

I am, Sir, yours faithfully,

London, W., Jan. 23rd, 1933. A. R. FRIEL.

MANCHESTER AND PASTEURISATION

To the Editor of THE LANCET

SIR,—Are we to remain apathetic while communities generally enlightened, such as Manchester, lose their "reputation for sound sense"? Your annotation (Jan. 21st, p. 152) makes me wonder what, after all, the medical profession as a body has done to lead public opinion on the pasteurisation of milk. If ever there was a case of "doctors differ, patients die," surely we have it here. The fine efforts of the Reading researchers have been made, through misrepresentation, partly responsible for Manchester's continuance to purvey tuberculous milk to the public.

The lead given by both the Ministry of Health and the expert committees working with the People's League of Health has shown us the road; Manchester in attempting to take that road has been worsted by the dragons in the path described as "organised vested interests." If the profession does nothing now it appears to be putting its own vested interests in alignment with those that have been successful in defeating Manchester's Bill. You invite Manchester to "think again"; but surely it is the whole medical profession up and down the country that should be thinking?

I am, Sir, yours faithfully,

ESTHER CARLING.

Berks and Bucks Joint Sanatorium, Peppard Common,
Jan. 23rd, 1933.

DERMATITIS FROM DYED FABRICS

To the Editor of THE LANCET

SIR,—Clinical observation and biological investigation have, I think, established that the dermatitis arising from the use of paraphenylenediamine and allied chemicals in hair and fur dyes is allergic in nature.[1] This clears the confusion which previously existed owing to the assumption that chemical irritation was causative.

The question of dermatitis arising from dyed fabrics must be dealt with on its merits as each case arises. The majority of cases will, no doubt, be dependent upon idiosyncrasy, as have all cases so far investigated by Dr. Killick and myself. The object of our paper (Jan. 14th, p. 77) was to draw attention to dermatitis resulting from the wearing of dyed fabrics, which had received little or no attention in the literature.

I am, Sir, yours faithfully,

Leeds, Jan. 21st, 1933. JOHN T. INGRAM.

INSTITUTE FOR THE SCIENTIFIC TREATMENT OF DELINQUENCY.—A lecture on the Law of Scotland with reference to Young Delinquents will be given by Mr. George Morton, K.C., at 8.30 P.M. on Friday, Feb. 3rd, at University College, Gower-street, London, W.C. Dr. J. A. Hadfield will preside and admission is free. Particulars of further lectures may be had from the hon secretary of the institute, 56, Grosvenor-street, W.1.

OBITUARY

SIR PERCY SARGENT, C.M.G., D.S.O.,
M.B. Camb., F.R.C.S. Eng.

SENIOR SURGEON TO ST. THOMAS'S HOSPITAL AND SURGEON TO THE NATIONAL HOSPITAL, QUEEN-SQUARE; VICE-PRESIDENT OF THE ROYAL COLLEGE OF SURGEONS, ENGLAND; HON. COLONEL, A.M.S.

IT is with sincere regret that we record the death in London on Sunday, Jan. 22nd, of Sir Percy Sargent, at the premature age of 59.

Percy William George Sargent was born in 1873, the eldest son of Mr. E. G. Sargent of Clifton, and was educated at Clifton College and St. John's College, Cambridge. In 1895 he entered St. Thomas's Hospital medical school, having obtained the University entrance scholarship. In 1898 he took the English double qualification, and in the same year graduated at Cambridge as M.B., B.Chir.; in 1900 he took the F.R.C.S. Eng. At St. Thomas's Hospital he had a brilliant record, and it is of interest that, while he was house surgeon, an astute observer, the late Mr. H. H. Clutton, predicted a great future for him in the surgical world—a prediction which has proved to be correct. He filled the junior posts at the hospital, and was appointed in sequence surgical registrar, resident assistant surgeon and demonstrator of anatomy, being elected in due course assistant surgeon. In 1905 Sargent, in coöperation with Prof. Leonard Dudgeon, gave the Erasmus Wilson lectures at the Royal College of Surgeons of England on the bacteriology of peritonitis, based on the work which they did together when Sargent was resident assistant surgeon, with unique opportunities for the investigation of the subject. The lectures were a forecast of Sargent's position. Those who were associated with Sargent and his work from his early surgical days realised that he had been provided by nature with the equipment—brains, eyes, and hands—essential for a great surgeon. He acquired a perfect technique, which combined with his clinical knowledge of surgery made it certain for him to gain a wide reputation in whatever sphere he elected to practise. It is not surprising that with such gifts he should have directed his attention at a comparatively early period of his career to neurological surgery, and in 1906 he was appointed assistant surgeon to the National Hospital, Queen-square. And not many years elapsed before Sargent was recognised as one of the outstanding personalities in the surgery of the nervous system.

SIR PERCY SARGENT

[Photograph by Hay Wrightson

With the outbreak of war, Sargent, in recognition of his special knowledge of cerebral surgery, was appointed consulting surgeon for head and spinal injuries to the B.E.F. in France. Here he worked in conjunction with Dr. Gordon Holmes, his colleague at Queen-square, who had been appointed consulting neurologist to the British Armies in France. Sargent was awarded for his services a D.S.O. in 1917, and received the C.M.G. in 1919. Some of the work performed in these critical times he recorded in the *Journal* of the R.A.M.C., but he was not a prolific writer, three papers, some sound articles on neurological surgery, and the articles on peritonitis and on the diseases of the vermiform appendix in Choyce's System of Surgery being his main contributions to medical literature. In 1928 the order of knighthood was conferred upon him, and in 1929, on the retirement of Sir Cuthbert Wallace from the staff of St. Thomas's, he offered his services to the medical school as part-time director of the surgical unit, being now senior surgeon to the hospital. His offer was welcomed by the governing body of the school, and he retained this appointment until a few weeks before his death. The students who had the opportunity to learn their surgery from him were fully conscious of the advantages which they were deriving. From the academic point of view he may not have been a great teacher, but his teaching was popular with the students because of the practical information he was able to impart, while his kindness to the many who went to him for help was little known to any outside his immediate circle, and was often unsuspected even by his colleagues at St. Thomas's.

Sir Percy Sargent was elected on the council of the College of Surgeons in 1923, and from that time gave much thought to the work of the College. In 1928 he was appointed a Hunterian professor and last year was elected vice-president, and throughout his term of office the affairs of the College of Surgeons were of primary importance to him. Among his other responsible posts, he was joint treasurer with Sir George Makins of the Imperial Cancer Research Fund, and hon. consulting surgeon to the Ministry of Pensions, while he had also acted as president of the neurological section of the Royal Society of Medicine. He examined in surgery at Cambridge, and had the reputation of scrupulous fairness. He gave a considerable amount of his time to work for the benefit of medical men and their dependents in financial distress, was honorary secretary of the Royal Medical Benevolent Fund and keenly interested in its development, and for many years intimately associated with the Invalid Children's Aid Association. He was a very keen Freemason, a Past-Master of several lodges, including the Cheselden and the Cliftonian, to the latter of which he had been secretary since its formation. In 1915 he was appointed Senior Grand Deacon of England. His easy manners and ready wit made him generally popular personally, and he was an excellent after-dinner speaker.

Sir Percy Sargent married in 1907 May Louise, daughter of the late Sir Herbert Ashman; her death in March, 1932, was a very serious blow to him; in fact, it is doubtful if he ever recovered from this loss. He leaves behind him two sons and one daughter, to whom we tender our sympathy.

A neurological colleague writes: "In the death of Sir Percy Sargent English neurology, and especially its surgical side, has sustained a serious loss. He was a direct successor of the founder of modern neurosurgery, Sir Victor Horsley, whose methods he studied conscientiously during the eight or nine years they worked together at the National Hospital, Queen-square, and adapted them to his own special aptitudes.

As Horsley and most other British surgeons who have specialised on the nervous system, he had the great advantage of coming to this branch fully trained and experienced in the principles and the technique of general surgery. Sargent's own special gifts were exceptional manual dexterity, rapidity in work and decision, accuracy and sureness of touch, and an imperturbability which carried him through many a sudden crisis and unforeseen difficulty. As his experience grew he became perhaps too conscious of the risk of radical operations in a field in which failure often meant disaster, but he was never bound by a rigid conservatism, and throughout his career he had few equals in the operative treatment of cerebral and spinal diseases.

"He rightly regarded his earlier years at Queen-square, when he frequently assisted and always worked in close collaboration with Horsley, as a period of training. His opportunity to put the experience he had then gained into practice came with the war, and he seized this opportunity promptly and with characteristic decision. As in the early days of the war the military authorities did not see their way to accept his special services, he went to France with the British Red Cross, and among the wounded of the battles of the Marne and Aisne studied the problems involved in the treatment of acute and often infected injuries of the nervous system, so that when he was later transferred to the R.A.M.C. as a consultant in neurology he was already familiar with the conditions on which he had to advise. His work in this sphere is too well known to need detailing; his tact, his obvious honesty of purpose, and his willingness to help in all circumstances made him a welcome adviser to hundreds of young surgeons. He took full advantage, too, of the opportunities provided by local lesions due to gunshot wounds to study many problems which could be less easily solved by the investigation of ordinary clinical material, and produced some noteworthy contributions to the scientific side of neurology. On returning to England he followed this work up in military hospitals, and later in the neurological hospitals of the Ministry of Pensions at Tooting and Richmond. It was on his work there that the well-known monographs on injuries of the peripheral nerves and of the spinal cord, published by the Medical Research Council, were largely based.

"At the end of the war his colleagues at the National Hospital, now without Horsley, were able to welcome him back and entrust to him much of the operative treatment of their patients. Here he worked continuously till his death, ever ready to give his best efforts to the care of his patients, and constantly anxious to adopt new methods which could improve or render more safe the operations which had gradually, as the years passed, become more complicated and more numerous. His manual skill remained unimpaired and at his death he was still at the height of his career as an operating surgeon. His recent resignation from the staff of St. Thomas's Hospital was welcomed by neurologists, as it was hoped that for many years Queen-square would have his undivided services, and that being able to devote more time to the work which interested him most he would place on record the results of his operations and the lessons to be learned from them. Unfortunately he has written little on neurology, as a busy professional life occupied his time fully, and a rigidly critical attitude towards his own work forbade him to put on record facts and opinions on which any doubt existed. His presidential address in 1921 to the section of neurology of the Royal Society of Medicine on epilepsy, and his papers on vascular tumours of the spinal cord and of the cerebellum are outstanding from his other valuable contributions to the literature. Sargent was universally recognised as a great surgeon and there can be no doubt he has left a lasting mark on neurology, but his chief monument will be the affection and respect he inspired in his professional colleagues and the gratitude of numerous patients who profited by his skill and were comforted by the confidence with which his personality imbued them.

"The outstanding features of his character were loyalty to his colleagues and a constant readiness to coöperate with them, devotion to the welfare of his patients, honesty in professional work and in private relations, and an optimistic enthusiasm which surmounted the disappointments which every neurological surgeon must meet. But to most of those who worked with him Sargent will best be remembered by his personal charm and his capacity for friendship."

MALCOLM EVAN MacGREGOR,
M.A. Camb., D.Sc.

WE regret to record the death of Dr. Malcolm MacGregor, director of the Wellcome Entomological Field Laboratories, Claremont, Esher (Wellcome Research Institution), which occurred at his home in Cobham on Jan. 12th, at the age of 43.

Malcolm Evan MacGregor was born at Port Elizabeth, South Africa, in 1889, the son of Robert MacGregor, of Durban, and his wife Clara Grace, daughter of Mr. John Redford, of London He received his scientific education at Trinity College, Cambridge, and Harvard, where he came under the influence of that great medical entomologist L. O. Howard and gained the Carnegie travelling fellowship in the subject, in which he also obtained a Cambridge research studentship in 1914. He first came into prominence during the war, when he served with the R.A.M.C. in East Africa in connexion with mosquitoes and other insect carriers of disease. From East Africa MacGregor was invalided home, and on recovery was placed in charge of a War Office Research Laboratory at Sandwich to study mosquitoes in their relation to the spread of malaria in this country from returned soldiers carrying the disease.

After the war he became the superintendent of the Entomological Field Laboratory, founded by Sir Henry Wellcome on the advice of the late Sir Andrew Balfour, director-in-chief of the Wellcome Bureau of Scientific Research. Here MacGregor continued his studies of mosquitoes, particularly with a view to solving some of the fundamental problems underlying their mode of life, feeding, hibernation, and reproduction. For a period these researches were interrupted by a visit to Mauritius on behalf of the Colonial Office to study the mosquito-malaria problem and to advise on methods of mosquito reduction. A valuable report on the conditions was submitted to the Colonial Office. In it was shown that a second important malaria-carrying mosquito occurred in Mauritius—namely, *Anopheles funesta*—which had been overlooked both by Ronald Ross and Andrew Balfour during their visits to the island. On his return to England MacGregor resumed his mosquito studies which have thrown considerable light on the food requirements and environmental necessities of these insects. He showed that the diverticulum, a sac which opens into the œsophagus of the mosquito, was a kind of reservoir into which the mosquito could direct at will or by reflex action fluids unsuitable for the stomach. He studied the extraordinary effect of ultra-violet rays on the larvæ, the various reactions of waters in which they occurred, and strove to establish the fact that the larvæ of culex and anopheles mosquitoes lived in waters of different but particular pH. Latterly he had been studying a so-called autochthonous race of *Culex pipiens,* a race which is able to complete its life-cycle without any blood meal, and which does not hibernate. These and other researches were in full swing at the time of his death and there was every promise that during the next few years most important and conclusive results would have been obtained. His death at the height of his scientific career, when many of his researches were about to bear fruit, is nothing short of a tragedy, inflicting a most serious loss upon the science of medical entomology.

Malcolm MacGregor was the author of numerous scientific papers dealing with the subjects of his particular study, and of a book entitled "Mosquito Surveys." He leaves a wife and two sons.

THE LATE SIR ROBERT JONES

Mrs. F. Chaplin Hall, secretary of the Association of Certificated Blind Masseurs, writes as follows: "No obituary notice regarding Sir Robert Jones, the famous orthopædic surgeon, is quite complete without reference to the important part he played in connexion with the blind massage movement in this country. The Association of Certificated Blind Masseurs, a professional body formed in 1919 to represent and safeguard the professional interests of blind masseurs and masseuses, had the honour to have Sir Robert Jones as its president from 1922, a position which he held up to the time of his death. The fact that Sir Robert consented to become the president was not only of inestimable value to the work of the Association, but gave a status and stimulus to the whole movement for massage by the blind. Sir Arthur Pearson, our first president, played the initial part in the formation of a band of educated blind men and women, comprising soldiers blinded in the war and men and women who had lost their sight in civilian life. Many of these took an active part in the treatment of the wounded in the later war period, and were anxious to band themselves together into a recognised body with strong medical backing. The death of Sir Arthur Pearson was a great misfortune for the movement, but Sir Robert Jones served us nobly."

Dr. Macalister writes: "Robert Jones began his career as a general surgeon, and at a very early age was on the staff of the Liverpool Stanley Hospital which he left in 1889 on appointment to the Royal Southern Hospital. It was here that he developed his orthopædic work to which from 1905 onwards he devoted his whole attention. He enlisted the interest of many workers in the out-patient department and also at his free Sunday morning clinics to which poor patients flocked from far and wide. His reputation as an original thinker and teacher brought surgeons from all over the world to his clinics and operations, which were always attended by large numbers of them. In connexion with his out-patient work he adopted the coöperation of the Child Welfare Association whose workers, after some training, kept an eye on the home conditions and feeding of the children. When a student his versatile capabilities were demonstrated at a very early period. He had a knowledge of literature far beyond that of his academic work, and this led to a capacity for debate which became cultivated in a small society, consisting of four students, which met at weekly intervals in the house of his uncle Mr. H. O. Thomas. Matters medical were, it is true, primarily discussed, mainly as a means of revising the week's work, but when these were completed papers were read and debated on literary, political, and social questions concerning which he in particular had very definite opinions. After qualification these four men invited other members of the profession and a number of laymen to join them, and thus in 1884 the progenitor of the Liverpool Medical and Literary Society, now approaching its jubilee, became formally constituted. One of the rules was 'The Society shall exist for the purpose of enabling its members to learn the art of speaking in public,' and there is no doubt that this object was and still is fulfilled. The membership of the society has included most of the leading members of the profession in Liverpool and many eminent in other work. Its 'after-meetings' were limited to a few enthusiasts who adjourned to a room in the basement and expended their pent-up physical energies by boxing, concerning which our friend was both an adept and an authority."

THE LATE MR. RICHARD GILL.—An error was made in our obituary notice last week with regard to the family of Mr. Gill's wife, Elizabeth Ann Bostock, who should have been described as the daughter of Deputy Surgeon-General John Ashton Bostock, C.B., of the Scots Fusilier Guards, honorary surgeon to Queen Victoria.

MEDICAL NEWS

University of Oxford

On Jan. 24th the degree of M.A. (honoris causâ), which was approved by convocation on Nov. 29th, 1932, was conferred on William Stobie, M.D. Edin. On Jan. 19th the degree of Bachelor of Medicine was conferred on H. F. Moseley.

University of Glasgow

The Harry Stewart Hutchison prize, of the value of about £50, for original research in a branch of medical science relating to children, will be awarded next year. The competition is not confined to members of the University of Glasgow. Particulars will be found in our advertisement columns.

Royal Sanitary Institute

At a sessional meeting of this institute, to be held at 90, Buckingham Palace-road, London, S.W., at 5.30 P.M. on Tuesday, Feb. 14th, Dr. J. S. Owens will open a discussion on Ventilation and the Need for New Standards.

The annual congress of the institute will be held at Blackpool from July 17th–24th under the presidency of Lord Cozens-Hardy.

British Congress of Obstetrics and Gynæcology

This congress will be held at Birmingham on April 5th, 6th, and 7th. The principal subject for discussion will be the Uterine Action and its Abnormalities.

Fellowship of Medicine and Post-Graduate Medical Association

Arrangements for next week will be found in our Medical Diary. A course of eight demonstrations on the Interpretation of Pyelograms will be given by Dr. G. Mather Cordiner, beginning on Wednesday, Feb. 8th, at 8 P.M. Forthcoming courses include a course in gynæcology at the Chelsea Hospital, Feb. 6th to 18th; a course in diseases of the chest, at the Brompton Hospital, Feb. 6th to 11th; a week-end course in physical medicine at the London Clinic and Institute of Physical Medicine, Saturday, Feb. 11th; and Sunday the 12th; and an evening course at the National Temperance Hospital, at 8 P.M., on Mondays and Fridays; Feb. 20th to March 17th. Lectures, courses, and demonstrations arranged by the Fellowship are open only to members, and further particulars may be had from the secretary of the Fellowship at 1, Wimpole-street, London, W.1.

World League for Sexual Reform

At a meeting to be held at the London School of Hygiene and Tropical Medicine, Keppel-street, W.C., at 8 P.M. on Wednesday, Feb. 8th, Dr. J. Leunbach, of Copenhagen, will speak on Abortion and Birth Control in Scandinavia.

Hospitals and Road Accidents

The Central Bureau of Hospital Information has, under legal advice, adopted a scheme which it is claimed will, if fully used, enable hospitals to recover up to £150,000 annually in respect of road accident cases. The plan, it is said, has already been adopted by a large London hospital and a small provincial one near a main road. The object is to get round the provision in the Road Traffic Act which limits the claim of a hospital against an insurance company to £25 by substituting a direct claim by the insured person. A reputable firm of local solicitors will be employed by the hospitals which will be responsible for the fees, and in return the patient will include in his claim the cost of his maintenance while in hospital. One of the advantages that it is hoped will result is the elimination of the "hospital chaser," the agent of a shady solicitor who follows up accidents in the hope of inducing injured persons to make claims through his principal. It is claimed that the scheme is applicable in all cases except the following: (1) hospitals whose constitution forbids them to make charges; (2) unwilling patients; (3) patients who for any reason are entitled to free treatment.

Hunterian Society

The annual dinner of this society will be held at the May Fair Hotel, Berkeley-street, London, W., at 7 for 7.30 P.M., on Thursday, Feb. 9th. The guests will include the Lord Mayor and the Lady Mayoress. The senior secretary is Mr. Andrew McAllister, 79, Wimpole-street, London, W.1.

North Staffordshire Royal Infirmary

The expenditure during the last financial year, the annual report states, exceeded the income by £7000, and there is now an accumulated deficit of £16,761. Ordinary income decreased by £1566, while ordinary expenditure rose by £2886. On the other hand, the extraordinary income was greater by nearly £12,000, mainly owing to a legacy of £10,000. There were 5896 in-patients, an increase of 451, and their average daily cost was 10*s.* 3*d.*, an increase of 10*d.* At 132,793 the out-patients' attendances fell by 11,320. In the special fracture clinic of the reorganised orthopædic department 2431 out-patients were registered, a large increase. The hospital is now a regional radium centre and accommodation for 12 male and 12 female radium cases has been provided, and the cases admitted from July 6th to Oct. 31st last year numbered 96. Private wards for 33 paying patients are to be provided immediately, the cost, £15,000, having been raised by an issue of 5 per cent. 20-year notes in multiples of £25 at par. Charges will range from four to eight guineas per week.

PUBLIC HEALTH SERVICES

Influenza

THE number of deaths from influenza reported from the 118 great towns in the week ended Jan. 21st was 1589, as compared with 120, 303, 681, and 1041 in the previous four weeks. For London itself the figure was 338, compared with 8, 25, 93, and 242 in the weeks before. In London, as already pointed out, no indication of unusual prevalence was observed until Dec. 24th–31st. During the week ended Jan. 14th the number of deaths from influenza in the 118 great towns corresponded to an annual death-rate of 2·64 per 1000. The rate for Greater London was less than this—namely, 2·36—whereas the midland area showed a rate of 3·25. The lowest incidence of deaths was in the south-west (0·91) and in Wales and Monmouthshire (0·98). The outbreak was still spreading, for only 8 of the 118 great towns failed to record a single death from influenza, compared with 29 in the previous week.

—	Ages 0–25		25–45		45–65		65 +		Total deaths
	Deaths.	Per cent.	Deaths.	Per cent.	Deaths.	Per cent.	Deaths.	Per cent.	
1932 Dec. 17th	15	17·6	9	10·6	21	24·7	40	47·1	85
" 24th	23	19·2	19	15 8	34	28 3	44	36·7	120
" 31st	43	14·2	70	23·1	89	29·4	101	33·3	303
1933 Jan. 7th	75	11·0	143	21·0	214	31·4	249	36·6	681
" 14th	112	10·8	196	18 8	336	32·3	397	38·1	1041

In Scotland, the infection has definitely abated in Glasgow, where in the week ended Jan. 21st there were 27 deaths, the figures for the three previous weeks being 86, 38, and 31. In Edinburgh the deaths during the corresponding four weeks numbered 5, 14, 25, and 19. Belfast reported 6 fatal cases in the week ended Jan. 14th, and on Jan. 17th the new notifications of influenza were stated to be 220.

In many parts of the country—though not in London—schools are closed, and although the infection is generally described as mild, it has been suggested that it especially attacks children and young people while it spares the old. It has been definitely stated, indeed, in one newspaper that the mortality is highest among the young, but no evidence of this appears in the accompanying Table, which shows the age-distribution of deaths from influenza up to the week ended Jan. 14th. It will be seen that so far the greatest proportion of deaths has been in the age-group 65 and over.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED JAN. 14TH, 1933

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 18 (last week 16); scarlet fever, 1739; diphtheria, 780; enteric fever, 21; acute pneumonia (primary or influenzal), 3456 (last two weeks 2017 and 2816); puerperal fever, 28; puerperal pyrexia, 143; cerebro-spinal fever, 47 (last week 38); acute poliomyelitis, 8; acute polio-encephalitis, 2; encephalitis lethargica, 7; dysentery, 6; ophthalmia neonatorum, 82. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on Jan. 17th–18th was as follows:—Small-pox 48 under treatment, 3 under observation (last week 52 and 7 respectively); scarlet fever, 1760; diphtheria, 1657; enteric fever, 10; measles, 274; whooping-cough, 524; puerperal fever, 25 (plus 7 babies); encephalitis lethargica, 229; poliomyelitis, 2; "other diseases," 317. At St. Margaret's Hospital there were 15 babies (plus 8 mothers) with ophthalmia neonatorum.

Deaths.—In 118 great towns, including London, there were no deaths from small-pox, 1 (1) from enteric fever, 27 (1) from measles, 8 (1) from scarlet fever, 40 (11) from whooping-cough, 30 (6) from diphtheria, 29 (9) from diarrhœa and enteritis under two years, and 1041 (242) from influenza. The figures in parentheses are those for London itself.

Outside London the largest number of deaths from influenza was again at Birmingham, where 91 were reported (last week 103). Other towns reporting numerous deaths from this cause were Manchester 49 (last week 22), Liverpool 41 (last week 23), Newcastle-on-Tyne 36 (last week 45), Portsmouth 35 (last week 19), Leeds 33(last week 14), Bristol 24, Gateshead 19, Coventry 16, Bolton and Stoke-on-Trent 15 each, Sheffield and Birkenhead 14 each, Barnsley and Sunderland 13 each. Measles caused 9 deaths in Birmingham and 3 in Liverpool. Five of the fatal cases of diphtheria were in Liverpool, and 5 of those from diarrhœa and enteritis were in Manchester.

The number of stillbirths notified during the week was 287 (corresponding to a rate of 45 per 1000 total births), including 41 in London.

Medical Diary

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

Thursday Feb. 2nd.—9 P.M., Mr. V. F. Hall: Modern Anæsthesia.

ST. MARY'S HOSPITALS, Manchester.

Friday, Feb. 3rd.—4.15 P.M. (at the Whitworth-street West Hospital), Dr. Fletcher Shaw and Dr. Bride: Antenatal Demonstrations.

GLASGOW POST-GRADUATE LECTURES.

Tuesday, Jan. 31st.—3.30 P.M. (in the Faculty Hall, [illegible] Prof. J. Hendry: Maternal [illegible] P.M. (at the Royal Hospital [illegible] White: Surgical Cases.

Appointments

Done, Janet M., M.B. Lond., has been appointed Resident M.O. to Horton General Hospital, Banbury.

Fison, J., M.D. Camb., Ophthalmic Specialist Medical Referee, under the Workmen's Compensation Act, for the Pontefract, Tadcaster, York, Ripon, and Harrogate County Court *Districts (Circuit No. 15).*

Mitchell, A. P., M.D., Ch.M., F.R.C.S. Edin., Medical Referee, under the Workmen's Compensation Act, for the Sheriffdom of the Lothians and Peebles.

London County Council.—Senior assistant medical officers (Grade II.): L. Houghton, M.R.C.S., Colindale Hospital; Smith, D. R. E., M.R.C.S., *St. Luke's Hospital, Lowestoft;* and Mitman, M., M.D. Lond., North Eastern Hospital. Assistant medical officers (Grade I.): Wesson, A. S., M.D., M.R.C.P. Lond., Archway Hospital: Dobbin, C. J. V., M.R.C.S., Bethnal Green Hospital; Fish, R. H., M.R.C.P. Lond., High Wood Hospital; Hargreaves, Flora, M.B. Lond., F.R.C.S. Eng., Mile End Hospital; Tanner, N. C., M.B. Brist., F.R.C.S. Eng., Lambeth Hospital; and Evans, R., M.B. Lond., Bethnal Green Hospital. [illegible] J. G., M.D. [illegible] M.B. Liver [illegible] W. J., M [illegible] Caplan, A., M.B. Lond., St. Pancras Hospital; and Kaufmann, Phyllis I., M.B. Manch., F.R.C.S. Edin., St. Charles' Hospital. Clinical [illegible] Ethelberta M., M.R.C.S., St. [illegible] physicians: Renbom, E. T., [illegible] St. Olave's Hospital; and Qui [illegible] St. Leonard's Hospital.

Births, Marriages, and Deaths

BIRTHS

Moncrieff.—On Jan. 19th, to Honor (née Wedmore), wife of Alan Moncrieff, M.D., M.R.C.P.—the gift of a son.

MARRIAGES

Blagg—Thomas.—On Jan. 16th, at St. James's Church, Piccadilly, S.W., Arthur F. Blagg, M.D., of Heathfield, Chilworth, Hants, to Mrs. Florence T. Thomas, of Carlton Mansions, Clifton, Bristol.

Little—George.—On Jan. 24th, 1933, at St. John's Presbyterian Church, Forest Hill, London, George Sinclair Ross Little, M.R.C.S., L.R.C.P., youngest son of the late Mr. David Little and Mrs. Little, of Cardiff, to Megan, eldest daughter of Mr. and Mrs. J. Evans George, of Forest Hill.

Paterson—Baxter.—On Jan. 23rd, at St. Columba's, Pont-street, S.W., Arthur Spencer Paterson, M.B., Swaylands, Penshurst, to Marie Antoinette Louise, daughter of the late Charles Baxter, W.S., and Mrs. Baxter, of Cheyne-walk, S.W.

DEATHS

Blair.—On Jan. 16th, at his brother's residence, Prestwich Mental Hospital, near Manchester, Matthew Cameron Blair, M.D., D.P.H., F.R.G.S., Honorary Consultant Nigerian Medical Staff (retired), and late Deputy Director, Sanitary Service, Nigeria.

Colby.—On Jan. 20th, suddenly, Francis Edward Albert Colby, F.R.C.S.

Grant.—On Jan. 16th, at Blackheath, after a long illness, Donald St. John Grant, I.M.S.

Sargent.—On Jan. 22nd, from pneumonia following influenza, Sir Percy Sargent, C.M.G., D.S.O., F.R.C.S., of Harley-street, London.

Thompson.—On Jan. 20th, suddenly, at East Sheen, Edward Charles Thompson, F.R.C.S.I., D.L.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

NOTES, COMMENTS, AND ABSTRACTS

NURSING EDUCATION IN MANY COUNTRIES

THE series of volumes on "Methods and Problems of Medical Education" which have been published at intervals since 1924 by the Rockefeller Foundation have been brought to a close for the time being. The fact that the final volume is devoted to nursing education and schools of nursing is of real importance, since it implies recognition of the development of nursing as closely bound up with medical education. The contents of the volume include 17 articles on methods of training nurses in different parts of the world, and the picture presented is a little one-sided, since as many as 10 of the 17 articles relate to nursing schools in the United States or Canada; but it is not less interesting on that account, since the aims of nursing education in America evidently differ considerably from those in the old world. The point which will immediately strike the medical reader is the academic trend of nursing education in America. Five university schools of nursing are described, at which it is customary for students to take the degree either of bachelor or master of science in nursing; such university courses are not for the rank and file, but are designed to train potential leaders —a sort of educational grading.

In an article on the Cook County School of Nursing, Chicago, Miss Laura R. Logan, the Dean, states that nursing education in America as a whole is "bound to the tradition of a hospital school, created only or largely to give service to that hospital"; but no account of such hospital schools of nursing is included in this volume, and it seems clear that leaders of nursing education in America believe the advancement of their profession to be closely linked with the development of university schools. Miss Annie W. Goodrich, Dean of Yale University School of Nursing, writes: "The importance of university relationship cannot be over-emphasised, for it has made possible within a comparatively few years an evolution of the program of nursing education that could be realised only through the freedom for study, experimentation, and demonstration that such a relationship permits." Much that such a programme entails would fall outside the scope of nursing education as understood in this country. At Cook County School of Nursing, for example, the curriculum of the first year student includes the study of chemistry, bacteriology, pharmacology, drugs, and solutions, and during the second year courses of lectures on psychology, sociology, and economics are attended. The view of a group of medical men, quoted in another article, that the nursing profession is trying to make half-baked doctors out of nurses is set down as an attempt on the part of the medical profession to protect its own interests. It appears, however, that this doubt has assailed one of the leaders of the American nursing profession; Miss Shirley C. Titus, Dean of Vanderbilt University School of Nursing, writes: "There seems to be a tendency to forget the fact that the real function of the nurse is the act of nursing the patient. It would seem that in the American hospital the nursing function has been made a minor function, and the service demands of hospital groups, other than the patient, have been made the nurse's major responsibility." She attributes this misdirection of the nurse's energies to lack of sufficient nursing personnel in hospitals where the director has economised by cutting down the nursing staff, but it seems possible that the clinical side of nursing has also been pushed into the background in a curriculum overweighted with scientific theory. It is repeatedly stated by the writers of these American articles that throughout training the nurse is impressed with the relation of her work to the health of the community at large, and in this respect there is no doubt that the American nurse receives a sounder education than nurses in the old world. The public health aspect of nursing is regarded, in this country at all events, as a separate study, and the young nurse in training is not given a very vivid conception of her relation to the welfare and health of society as a whole.

The article by Miss Heaton on nursing in England included in this volume provides a good if necessarily condensed account of present conditions of nursing education in this country. Her survey includes an account of the syllabus for and conduct of the examinations leading up to State registration; of the preliminary training schools which some 60–70 hospitals have now established; of the supplementary parts of the State register; of the training of tuberculosis nurses; of post-graduate courses available for nurses; of hospital finance, and present-day tendencies in nursing. Her statement in a brief section on hours of work that it is customary to allow 45 minutes to nurses in training for midday dinner is unfortunately not true. Replies to the questionnaire issued by THE LANCET Commission on Nursing showed that in two-thirds of the hospitals only half an hour was allowed for this meal; and the recommendation of the Commission that this time should be extended to at least 40 minutes was evidently offered as the maximum time which would be likely to be conceded by hospitals throughout the country.

The training of nurses is evidently in a transitional stage in all countries; but it is safe to prophesy that where it is inspired by academic ideals to the neglect of clinical experience it will not provide the complementary service which medicine demands.

AN EMPIRE PROBLEM

THE material betterment of the conditions of native races is the aim which inspired Prof. Blacklock to write an essay on the house and village in the tropics.[1] He is anxious to create and maintain public interest in the development of the tropics, and suggests that an annual exhibition in London, where the existing village defects of various tropical countries could be fully demonstrated on the model of the Ideal Home Exhibition, would be a useful method of propaganda. In this book he does not deal only with housing, but discusses the growth of tropical medicine, the staffing of hospitals and medical services in the tropics, and the relation of tropical medicine to trade.

A section is devoted to a consideration of the native house and its attendant parasites, the jigger, the flea, the Tumbu fly, the Congo floor maggot, and various species of tick and bed-bug. The parasites which infest the roof (rats, ants, and other insects) are also considered, and the water-supply, which may convey cholera, typhoid, both forms of dysentery, ankylostomiasis, bilharziasis, or the Guinea worm.

This useful little work closes with a popular account of malaria, elephantiasis, sleeping sickness, and other filarial diseases. An entertaining chapter concerns the skin of the native child who, from the hour of its birth upwards, is subjected to a perpetual series of injuries and pin-pricks of every kind; this is an aspect of medicine to which too little attention has so far been paid. It would be interesting to pursue this study on psychological lines; such questions as the effect of the darkness of the tropical village, and of the impossibility of obtaining mental relaxation during the long hours of the night, are worth consideration. It is small wonder that the African often becomes a prey to the native magician. Those who intend to live in tropical Africa will do well to read this book, and even old-established residents there will find in it a fresh point of view.

Factors Affecting the Mortality of Burns

Before dealing with the mortality of burns and scalds, there are two important factors to be considered irrespective of the method of treatment used.

The first of these, as pointed out by Donald,[1] is that the improved social conditions in the homes of the poor, and the disappearance of the open light and open fire have done much to diminish the number and severity of burns coming for treatment to the great hospitals of the metropolis. Taking the figures from 1899–1903 at the London Hospital, he has shown that the mortality for the 999 burns and scalds admitted during those years was 25·3 per cent., whereas in 1924–28 the number of admissions had diminished to 286, or rather less than one-third, and the mortality had dropped to 6·6 per cent., although the treatment used was practically the same during both these periods. This he attributes largely to the passing of the Children's Act in 1908, which made it a punishable offence to leave a child alone in a room containing an open fire grate insufficiently protected, and he pointed out that in the years 1909–13, immediately following the passing of this Act into law, the number of burns admitted to hospital diminished by 50 per cent.

At St. Thomas's Hospital the figures are by no means so conclusive, for though the number of burns and scalds treated as out-patients is slightly smaller, the number of burns and scalds admitted to the hospital has remained very steady throughout a number of years, both before and after the passing of the Children's Act in 1908, and has been approximately 60 per annum from the year 1894 onwards

that whereas the average mortality for burns over the period of years from 1894–98 was 40 per cent., that for scalds for the same period was only 19 per cent. Again, during the period from 1900–1903 the average mortality from burns was 39·7 per cent., whereas from scalds it was only 7 per cent. Here it is of interest to note that in 1899 (Table II.) picric acid was used for burns and the mortality fell to 33 per cent., but the mortality of scalds, still for some reason treated by old methods, was 40 per cent. Again, from 1924–28 (Table I.) the mortality for burns was 15·5 per cent., but for scalds only 7·5 per cent., and from 1929–32, inclusive, the mortality was, burns 4 per cent., scalds 1·7 per cent.

The Registrar-General's mortality figures are unfortunately not helpful, for they give the number of deaths per million of population, and offer no indication of the relative number of non-fatal burns and scalds. They show a greater number dying from burns than scalds—20·8 burns and 18 scalds per million, all ages. It is startling and unexpected to find that the female deaths from burns are just over twice as great as the males throughout the period (1924–31), while in the case of scalds the proportion is 2 females to 3 males. Further, whereas the number of burns to scalds in the first period (1894–98) was 275 burns to 202 scalds, in the second period (1900–1903) it was 239 burns to 172 scalds; and in the third

Feb. [illegible]
[illegible]ve attributed the untoward conditions to the wrath of Heaven in consequence of the introduction of the toy named "Yo-Yo" which gained universal popularity recently. The toy or contraption, whose vogue is now, we think, exhausted, was a sort of bobbin or spool of wood which is made to rise and fall by manipulating a string wound round the spindle of the bobbin. The Moslem priests maintained that "while people were praying for rain to come down from above the Yo-Yo goes down, and before reaching the ground up it springs again." Hence, of course, the drought, the rain, in mimicry, going up again before it has come down. In consequence of the protest by the priests the Minister of the Syrian Republic has prohibited the game, and the police have confiscated all "Yo-Yo's" seen in the streets. The sequel has been that during the Moslem week and on the sacred day of that week in central Iraq, where the drought had been most severe, rain fell heavily, and the accuracy of the religious divination has been proved to the Syrians.

St. Bartholomew's Hospital, E.C.—Asst. Surgeon.

St. Benedict's Hospital, Church-lane, Tooting, S.W.—Asst. M.O. £250.

St. George-in-the-East Hospital, Raine-street, Wapping, E.—Asst. M.O. £250.

St. Luke's Hospital, Sydney-street, S.W.—Asst. M.O. £250.

St. Mary's Hospital for Women and Children, Plaistow, E.—Hon. Ophthalmic Surgeon.

St. Paul's Hospital for Diseases of the Genito-urinary Organs and Skin, Endell-street, Holborn, W.C.—H.S. At rate of £150.

St. Thomas's Hospital.—Res. Asst. Physician.

Salisbury General Infirmary.—Two H.S.'s and H.P. Each at rate of £150.

Southampton Children's Hospital and Dispensary for Women.—Res. M.O. At rate of £150.

Southend-on-Sea General Hospital.—Res. Obstet. House Officer.

Stoke-on-Trent, North Staffordshire Royal Infirmary.—Asst. H.P. £125.

Sudan Medical Service.—Two M.O.'s. Each £E720.

Swansea County Borough.—Asst. M.O. £500.

Walsall General Hospital.—H.S. At rate of £150.

West London Hospital, Hammersmith-road, W.—Asst. Phys. for Diseases of Children. Also Asst. Gynæcologist.

The Chief Inspector of Factories announces vacancies for Certifying Factory Surgeons at Caldicot (Mon.), Fleet (Hants), Romsey (Hants), and at Banff (Banff).

The Home Secretary gives notice of vacancies for Referees *at each of the following Sheriff Court Districts or groups of* Districts: Campbeltown; Dunoon; Kirkcudbright; Cupar; Glasgow, Lanark, Hamilton, and Airdrie; Dingwall, Tain, Cromarty; and Duns. Also for Ophthalmic Cases at Ayr, Kilmarnock; Glasgow, Lanark, Hamilton, and Airdrie; Paisley, Greenock, and Rothesay; and Stirling, Falkirk, Dumbarton, and Alloa. Applications should reach the Private Secretary, Scottish Office, Whitehall, London, not later than Feb. 11th.

37·2 per cent., Harris,[7] and 35·4 per cent. at Edinburgh, Wilson [9]).

Following the introduction of the picric acid treatment for burns by, I believe, Sir Cuthbert Wallace in 1899, the mortality at St. Thomas's Hospital during the succeeding four years, as seen from Table IIIA., diminished considerably for scalds, showing an average for the period of 7 per cent., that of burns remaining at 39·7 per cent.; while in a corresponding five-year period immediately preceding the introduction of tannic acid the mortality for burns had fallen, I think partly owing to the introduction of adequate preliminary cleansing of the damaged area, partly to improved social conditions and the change in the proportion of burns to scalds (Table III.B) to 15·5 per cent., while that for scalds remained approximately the same at 7·5 per cent. No exsanguination transfusion was carried out on these cases.

TABLE III.—*Mortality of Burns and Scalds in St. Thomas's Hospital* (A, 1900–03; B, 1924–28).

Treatment.—2 per cent. aqueous picric acid for two or three days, then paraffin dressings in most cases.

* In addition, treated with 2 per cent. tannic spray, 7 burns and scalds with 1 death—14·2 per cent.

These figures compare very favourably both with the figure quoted by Wilson [9] for the Edinburgh Royal Infirmary (22·4 per cent.) during the same period, and the Sick Children's Hospital, Toronto (29·6 per cent. in 213 cases), where exsanguination transfusion was used combined with local treatment.

What then was the reason of this improvement in mortality where picric acid 2 per cent. aqueous solution was used unless that the coagulation of the surface protein both lessened collapse and stemmed the escape of serum?

Considerations in Treatment

The treatment of burns and scalds therefore, following adequate cleansing of the damaged area, aims, in the main, at lessening the collapse by stopping the absorption of those bodies which cause this collapse and death in from 12 to 48 hours after the burn, and also in diminishing the loss of fluid from the burnt area which, as has been shown, is so serious and so often fatal in the first 6 to 12 hours.

A further aim is prevention of the toxæmia from absorption of septic material from the infected burnt area which may be manifested elsewhere, especially as septic broncho-pneumonia, and cause death in from 5 to 12 days.

The initial shock and suffocation cannot be affected by local treatment of the burnt area, and death from these causes can be ameliorated only by efficient first-aid treatment from those on the spot at the time of injury.

Tannic Acid Treatment

When I was in Detroit in 1926 I was privileged to see Dr. Davidson's treatment of burns by compresses of tannic acid solution, and I was very much struck with the fit condition of the patients and the absence of sepsis resulting from this treatment. I was, however, convinced that a treatment which necessitated the removal of the protecting scab with the dressings at frequent intervals, with considerable pain to the patient, was not ideal.

On taking over the charge in November, 1928, of the septic wards at St. Thomas's Hospital, to which all the burns and scalds are admitted, I adopted the spray method advocated by Wilson,[2] saving that I found a 2 per cent. solution of tannic acid was adequate to secure good results. I was immediately struck by the enormous improvement in the general condition of the patients and the entire absence of pain and sepsis in the areas so treated. It was a noteworthy fact that patients with very extensive burns and children with scalds were comfortable, bright, and alert the day following the injury, read, talked cheerfully, and ate well, while the pulse was not rapid, nor the temperature raised.

TABLE IV.—*Mortality of Burns and Scalds in St. Thomas's Hospital* (1929–32).

Treatment.—2 per cent. tannic acid, 1/2000 mercuric chloride; spray *or* compress.

	No.	Deaths.	Per cent.	No.	Deaths.	Per cent.
1929	12	0	0	27	0	0
1930	15	1	6·6	37	2	5·4
1931	21	1	4·7	53	1	1·8
1932	26	1	3·8	58	0	0
Total 4 years..	74	3	4·0	175	3	1·7

It was obvious, however, that there were many disadvantages to this method of treatment, to wit, (*a*) the necessity for leaving the area exposed to the air while at the same time keeping it and the patient warmed; (*b*) the disadvantage of the mechanical restraint necessary to keep the damaged area at rest and free from interference and irritation: (*c*) the need for constant attention and repeated hourly sprayings for from 10 to 24 hours (and usually, in my experience, nearer the latter period of time); (*d*) the obvious impossibility of being able to spray and expose the entire burnt or scalded surface in those cases where the body had been burnt both in front and at the back; (*e*) and—a minor detail—the necessity for hourly making of fresh solutions. This last was necessary, as I discovered that with solutions kept after this time the crust produced was soft in consistency, light in colour, and though it gave an equally satisfactory result as when constant fresh solutions were applied, yet the patient suffered some pain and inconvenience which could be avoided under the rigid period (1924–31) it was 132 burns to 360 scalds; showing that the total number of burns and scalds admitted to St. Thomas's has remained very constant, yet there is a considerable increase in the number of scalds to burns—a factor the importance of which must be realised when considering the mortality of these cases apart from the method of treatment adopted, and one which I venture to point out has so far apparently escaped notice. It is, however, of some importance, for I find that whereas some writers by "burns" mean burns only, others include scalds under this heading, a proceeding which vitiates the value of comparative tables.

Causes of Death from Burns

In considering the causes of death from burns, as they have been admirably summarised by Wilson,[2] we have the stage of initial shock (or, as I prefer to call it, "shock") which immediately follows the upset to the nervous system resulting from the exposure to flames or scalding fluid. He estimates the mortality in this period as only 2½ per cent. The experience at St. Thomas's Hospital places it even slightly lower in those cases which survive to be admitted to hospital, though Donald gives this figure as far higher and increasing from 30 per cent. (1899) to 58 per cent. (1928).

Secondly, the stage of acute toxæmia due to the absorption of toxic substances from the damaged tissue in the burnt or scalded area. Here the experience at St. Thomas's Hospital leads one to agree emphatically with Wilson's opinion that this occurs 6 to 24 hours subsequent to the injury, and not as stated by Fraser [3] on the fourth day or later. As has been shown by Davidson [4] and Fraser,[5] this toxæmia is the result of histamine freed into the blood from damaged tissues which possibly causes diminution of blood chloride, and is best combated, if and when it has occurred, by exsanguination transfusion as suggested by Ajello and Parascando,[6] and advocated and practised with such success by Fraser,[5] Harris,[7] and others. This method, which consists in removing a measured quantity of the toxic blood from the patient and replacing it by a somewhat larger volume of whole blood from a donor, is not necessary if by coagulation of the damaged tissues we can prevent absorption toxæmia. It is therefore unnecessary, as will be shown, in the treatment of burns the surface of which has been sufficiently coagulated with tannic acid.

There is, however, at an earlier period (6 to 12 hours) a very important factor which seems to have escaped the attention of Wilson, for he does not mention it. Attention is however devoted to this subject by Underhill,[8] who discovered that the loss of blood-serum from the burnt surface in the first hours after a burn is very excessive—a fact well known clinically and demonstrated both by the condition of the dressings on the burns and the extreme thirst and restlessness of the patient. Underhill showed that with rabbits this loss may reach 70 per cent. of the blood volume, that the maximum loss occurred with third degree burns of large extent, moreover that where one-sixth of the total surface is burnt death almost inevitably follows. In analogy, a man of 65 kg. body-weight who might be expected to have 5000 c.cm. of blood in his body would lose 3500 c.cm. of serum in the 24 hours following a third-degree burn, involving one-sixth of the total body surface, and the majority of this loss occurs in the first 12 hours. It will be seen therefore that this factor constitutes a very potent cause of that collapse which subsequently ensues and which is responsible for something like 80 per cent. of the deaths after burns. This collapse is due both to the toxic absorption and this extensive loss of fluid from the burnt area.

The excessive loss of serum may be combated by the administration of fluid intravenously, subcutaneously, and orally, but with an extensive burn it is next to impossible to get sufficient into the tissues to replace the loss, and it is essential therefore that some method of combating this loss, such as coagulation of the surface of the burnt area, shall be devised which will be sufficient, both mechanically and physically, to prevent the escape of fluid from the capillaries on the surface of the damaged tissues. It was, I think, here that the picric acid treatment constituted such an advance on the older bath and grease method, though it failed inasmuch as the coagulum did not penetrate the tissues to prevent the absorption of toxic substances from the deeper tissue damaged in the accident. Again, owing to the toxicity of the picric acid, manifested by skin rashes, irritation, and not infrequently by albuminuria, it was seldom possible to retain this dressing more than two or three days, after which paraffin had to be substituted and sepsis not infrequently supervened.

Thirdly, there is the stage of septic toxæmia which constituted so serious a problem in the few cases which in the old days survived the previous stage. This is not a serious problem if the injury is treated by picric acid, and is practically non-existent in the tannic acid treatment, where with proper and adequate preliminary cleansing of the damaged area sepsis is practically never seen.

Reasons of Failure of Older Methods of Treatment

The practice at St. Thomas's Hospital before 1899 was to treat all burns by daily baths, with the object of washing away septic material, and applying an antiseptic grease dressing between these periods in an endeavour to obtain a painless dressing and a vain hope of preventing the suppuration which invariably occurred. But no local treatment was present either to prevent the absorption of collapse producing histamine bodies, or to stop the escape of serum from the damaged tissues. As will be seen from Table II., the average mortality during these years for burns was 39·6 per cent., and for scalds was 18·8 per cent. (compared with the Sick Children's Hospital, Toronto,

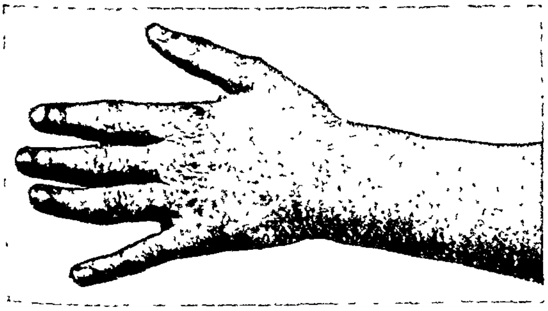
lysis and 73 per cent. unaltered gallo-tannin, and that the percentage of gallic acid in solutions of earlier date is considerably less, I have been convinced that change to gallic acid does not occur to any appreciable extent. Moreover, this hydrolysis to gallic acid takes place extremely slowly in solutions free from moulds, which do not develop in those containing 1/2000 perchloride of mercury, and it has been shown that in a three-months-old 2 per cent. solution with 1/2000 perchloride of mercury no practical increase occurs in the percentage of gallic acid. Incidentally, on sterilising and using the five-year-old solution above referred to on a burn, as a compress, a good scab was obtained with a perfect result.

A further possible cause for failure of the stale solution was that owing to an increased density of colloid a solution of diminished strength only could get through the nozzle of the atomiser, but this was easily disproved. Then was it possible that oxidation was causing some change in the solution though none was demonstrable? A solution was charged with carbon dioxide to prevent this possible oxidation, and though this remained quite free from those traces of pyrogallol which cause the darkening of any tannic acid solution exposed to the air, the crust produced was not in any way different to that obtained from using the ordinary stale solution of tannic acid, it was softer and lighter in colour.

FIG. 3



Slight scald of hand. Showing complete epithelialisation on removal of compress at end of 10 days.

It was obvious, therefore, that no apparent change occurred in the solution, and I considered that probably longer contact of the solution with the area should result in a satisfactory coagulum, and, as already stated, observations proved this surmise to be correct. It struck me when I found that the burnt surface, covered by a sterile gauze dressing, of a patient lying on a sheet soaked in the overflow from the tannic acid sprayed on the damaged and exposed area, formed a perfectly good crust, that herein lay a possible easy method of treatment. By the sacrifice of a soiled sheet I evolved the method of treating these burns and scalds with a compress left undisturbed on the previously cleaned area until the scab separated, usually in from 14 to 21 days (Figs. 1 and 2).

In order to prevent the growth of the moulds in the tannic acid solution, and so diminish the hydrolysis to gallic acid and at the same time to keep an antiseptic in the area and possibly so minimise the chance of sepsis from outside sources, I looked round for some suitable antiseptic to add to the 2 per cent. tannic acid solution. Here I was helped by previous experience and decided to use the 1/2000 perchloride of mercury, which again proved quite efficient in inhibiting growth of moulds and so reducing hydrolysis to a minimum, while it also acted as an efficient antiseptic in the coagulum and so prevented outside infection. I again found that when added in a strength of more than 1/2000 the perchloride interfered with the coagulating action of the tannic acid and produced a soapy crust which was unsatisfactory and did not relieve the patient's pain.

TECHNIQUE OF THE COMPRESS METHOD

A compress of 2 per cent. tannic acid with 1/2000 perchloride of mercury makes a most efficient first-aid dressing for all burns and scalds, as I have proved in my own home. But in the home and other places where burns occur but rarely, tablets or powder, to be dissolved in warm water and applied by soaking clean linen in the resulting solution, will be found more advantageous than keeping a large quantity of stock 2 per cent. solution.

The formulæ for the tablets and powder are as follows :—

Powder: tannic acid, grs. 17½; perchloride of mercury, gr. ½; to be dissolved in 2 oz. of warm water, when a 2 per cent. solution will result.

Tablets: tannic acid, grs. 17½; perchloride of mercury, gr. ½; boric acid, gr. 1; to be dissolved in 2 oz. of warm water, when a 2 per cent. solution will result.

Whatever method of first-aid treatment may have been employed—and I hope as time goes on the method I am about to describe may become universally adopted as a first-aid dressing—it is essential that this first-aid dressing, even if of tannic acid, should be removed, which it can be most easily, and the area carefully cleaned before the final tannic acid dressing is applied. By this careful cleansing alone can subsequent sepsis be avoided; and here let me say that should sepsis supervene during a course of treatment, it is only necessary to remove the tannic acid dressing, re-clean the area thoroughly, and

15–20 „ ..	Tinct. opii *and* Inj. morph.	♏ xxx. gr. ¼.
Over 20 „ ..	Tinct. opii *and* Inj. morph. (*b*) *or* Inj. morph. (*c*).	♏ xxx. gr. ¼–⅓. gr. ⅓–½.

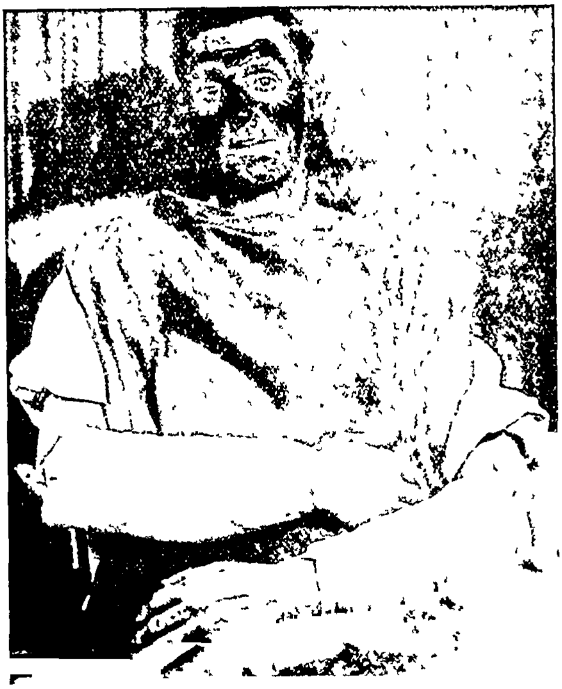
Remarks.—(*a*) Tinct. opii is more satisfactory than morphia. (*b*) For women. (*c*) For men according to stamina.

N.B.—Should slow or shallow breathing give rise to anxiety, atropine sulphate gr. 1/200–1/50 should be administered hypodermically.

black coagulum obtained with repeated applications of freshly made 2 per cent. tannic acid.

These facts made this method of treatment applicable only in the case of in-patients in large hospitals, and possibly the offspring of that diminishing class, the millionaire, and even in these cases only to those patients who were sufficiently thoughtful to be burnt on one side alone. I therefore set about to try to discover some other method which should be applicable universally to the treatment of burns and scalds in the out-patient departments, by general practitioners, and both at home and in works as a first-aid application. And here I was helped by the suggestion of a compress for first-aid in the Medical Research Council's report.[10] It struck me that if an antiseptic were added it would enable the solution to be made with clean tap water, and prevent possible infection from outside sources. I was further guided in the choice of an antiseptic by the knowledge that perchloride of mercury was a precipitant of proteins, and indeed, on inquiry, I found that Petit, and I believe also Lord Lister, had in the early part of the nineteenth century employed perchloride of mercury as a treatment for burns with the object of precipitating surface protein by an antiseptic and so preventing toxic absorption and local sepsis. Owing, however, to the toxic nature of the mercury solution all those cases had either died or suffered severely from mercurial poisoning, and this method of treatment had been abandoned. I found, however, that when added in a strength of more than 1/2000, the perchloride of mercury interfered with the coagulating action of the tannic acid and produced only a soft soapy crust, which was unsatisfactory and did not relieve the patient's pain or completely prevent collapse.

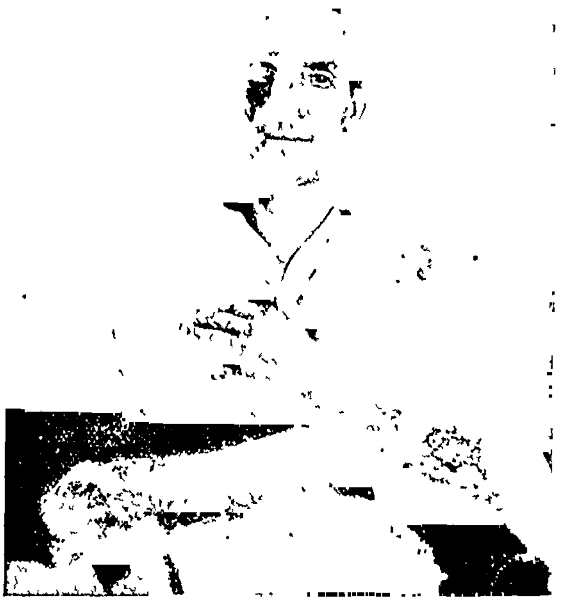
FIG. 1



Severe third and fourth degree burn. Ten hours after injury. Face sprayed; arms "compressed" (a clean bandage is applied over the stained compress and bandage).

I therefore commenced in the autumn of 1929 to use in the out-patient department compresses soaked in 2 per cent. tannic acid and 1/2000 perchloride of mercury for the treatment of all minor burns and scalds. These were made of lint or gauze but I have found the latter more satisfactory, and at first this was re-wetted on the outside hourly for six or eight times with freshly made solution. This frequent damping was inconvenient with out-patients, even though I had tablets made for the patients to take home with them. Further investigation has shown this re-damping to be unnecessary to the success of this method, which has been for over three years in almost universal use in both the in- and out-patient departments of St. Thomas's Hospital, and latterly it has been in use by several general practitioners and as a first-aid dressing in various works, and in my own home, where it has proved satisfactory.

FIG. 2



The same patient 14 days later. Coagulum and compress removed.

CHANGES OF TANNIC ACID AND ITS SOLUTIONS ON KEEPING

The next thing that occurred to me was why a fresh solution was necessary hourly? On analysis of the tannic acid used at St. Thomas's Hospital, it proved to be a natural gallo-tannin prepared from Aleppo galls, and to contain when fresh 88 per cent. gallo-tannin and 6 per cent. gallic acid, and some moisture. Thanks to the aid of Prof. R. H. A. Plimmer and Mr. J. Lowndes, of our chemistry department, I soon knew that even at the end of two years no change had taken place in the colloidal state of the tannic acid solution, and it was necessary therefore to seek some other explanation as to why a stale solution gave an unsatisfactory crust. Frankly I have not been able to find it. In this investigation I have had the help of Mr. C. W. Peck, the pharmacist at St. Thomas's Hospital, and the great assistance of Mr. W. A. Woodward, one of the dispensers. Mr. Woodward, working by the colorimetric method advocated by Ainsworth Mitchell,[11] has shown that even after five years a 2 per cent. solution of tannic acid contains no more than 8·45 per cent. of gallic acid as a result of hydro-

If we consider the mortality in the case of children under 10 years (Table VI.), and compare them with those in the late picric acid period, it will be seen that the results with burns are not good as with scalds—a point analogous to the transition from oil to picric acid (compare Table II. and III.A). The results, however, show a distinct amelioration, and lead one to hope that further reduction in mortality may take place, and it must moreover be realised that these figures are for the severe burns alone. The Edinburgh figures (combined) for the same period are 8·7 per cent. (1926-29), 5·8 per cent. (1930), and 4·8 per cent. (1931), against St. Thomas's (combined) 3·7 per cent. (1929–'32), and Sick Children's Hospital, Toronto, 16 per cent. in 230 cases (1925–28).

I would add that during the period 1929 to the present time, when tannic acid compresses have been the routine out-patient treatment for all burns and scalds, no deaths have occurred among those slighter cases which average 800 a year, of which about one-third are in children under 10 years of age. As might be expected there is a seasonal incidence of approximately 3 : 2 in favour of the winter months. For the past three years, then, the compress method has been in use in the out-patient department at St. Thomas's Hospital with excellent results. I regret I cannot give details either of the number and type of cases treated nor of the exact degree of severity of the burns and scalds; but in only two cases has sepsis occurred of a sufficiently severe nature to call for the admission of the patients to the wards, and in both these cases cleansing and reapplication of the tannic acid dressing has led to an uneventful recovery.

TABLE VI.—*Mortality of Burns and Scalds under 10 years in St. Thomas's Hospital*

Treatment.—1924–28, picric acid 2 per cent.; 1929-32, tannic acid 2 per cent. $HgCl_2$ 1/2000.

Year.	Burns.			Scalds.		
	No.	Deaths.	Per cent.	No.	Deaths.	Per cent.
1924	7	1	14·2	23	0	0
1925	7	2	28·4	26	3	11·5
1926	7	0	0	32	3	9·3
1927	5	1	20 0	30	5	16 6
1928	6	0	0	23	3	13·0
Total 5 years..	32	4	12·5	134	14	10·4
1929	3	0	0	23	0	0
1930	3	1	33·3	34	2	5·8
1931	14	1	7·1	38	1	2·6
1932	7	1	14·2	41	0	0
Total 4 years..	27	3	11·1	136	3	2·2

I venture to think that this simple method of compress may be of universal application both by the general practitioner, in the out-patient departments of hospitals, and as a first-aid treatment in works and in the home, presenting, as it does, in its simplicity great advantages over the more complicated method of reinforced compresses recently advocated by Hunt and Scott[12] and Wilson.[9]

In the foregoing remarks I have endeavoured to trace the progress of the treatment of burns and scalds during the past 40 years, and to show that although improved social conditions and an increase in the number of scalds have, done much to reduce this mortality, yet improved treatment has done more, especially the introduction, or should I say rediscovery, of the value of tannic acid in this relationship. I have described a simple method of using this tannic acid, and even if you do not consider it suitable for universal application, as I hope you may, you must admit that its success in reducing the mortality of severe burns and scalds to 4 per cent. and 1·7 per cent. respectively at least redounds to the credit of the local treatment, for social conditions remain the same as in the preceding five years when the mortality was considerably higher (15·5 per cent. and 7·5 per cent.).

Further, may I urge the necessity of separating the figures relative to the treatment of burns from those of the treatment of scalds in papers dealing with this subject.

Finally, I wish to tender my thanks, in addition to those already mentioned, to my successive house surgeons, Messrs. R. W. Butler, R. O. Lee, T. H. Wilson, R. H. Franklin, and T. W. Mimpriss, and especially to Miss Routh (sister of the septic wards), to whose patient care and continued enthusiasm much of the success of this treatment has been due.

IDIOPATHIC APLASTIC ANÆMIA

WITH AN ANALYSIS OF FOUR CASES

BY F. GRAHAM LESCHER, *M.C.*, M.D. CAMB.
PHYSICIAN TO THE DERBYSHIRE ROYAL INFIRMARY

AND

DOUGLAS HUBBLE, M.B. LOND.
ASSISTANT PHYSICIAN TO THE DERBYSHIRE HOSPITAL FOR SICK CHILDREN

APLASIA of the bone-marrow is a condition in which the hæmopoietic function of the marrow has become depressed, so that there is a diminution in the output of those blood-cells which are derived from it—i.e., the erythrocytes, the granulocytes, and the platelets.

It is not so much a disease-entity as a state produced by many conditions, such as poisoning by benzol and its derivatives; excessive exposure to irradiation; exhaustion of the bone-marrow by certain types of anæmia, such as hæmolytic anæmia and those anæmias with a megalocytic blood picture; and certain diseases which may affect the bone-marrow such as tumours and leukæmia. These conditions so depress the function of the bone-marrow that it ceases, to a greater or lesser extent, from performing its task of producing blood-cells. It is said that sepsis can produce aplasia. This and the pathogenesis of aplastic anæmia have been discussed elsewhere.[1]

But when these conditions of known ætiology have been excluded, there remains one type of aplasia, consistent in its symptoms, blood picture, and clinical history, and of no known causation, which may be regarded as a disease entity, and to which the term reapply a new tannic acid dressing in order to get a good result.

The cleansing must start with the removal of all dead and charred tissues, the excision of all loose skin raised over blisters, and the removal of grease, especial attention being given to the edges of the damaged area. The whole area should then be gently but thoroughly cleansed with soap and water (applied with a sterile swab and *not* with a nail-brush) and finally carefully sponged over with ether, to remove all natural or applied grease, in order to get a thorough coagulation. It is obvious that this treatment cannot be carried out unless the patient is rendered insensible to the pain which such a cleansing of the damaged area must entail. We have found at St. Thomas's that it is safer and more satisfactory to procure this insensibility by the administration of large doses of opium rather than the use of general anæsthesia which tends, even with the greatest care in its administration, to be followed by pulmonary complications, usually of a mild nature, which are detrimental to the rapid recovery of the patient. Table V. indicates the dosage and drug employed at various ages, and has proved both safe and satisfactory.

APPLICATION OF COMPRESS

A compress consisting of either six layers of sterile gauze or three layers of lint should be thoroughly soaked in a stock solution of 2 per cent. tannic acid and 1/2000 perchloride of mercury, and applied closely and evenly over the entire burnt area without wringing the dressing out. This compress should then be firmly and evenly bandaged in position, the bandage being applied directly to the outer side of the compress. The whole of the outside of the bandage may then be soaked with a spray of 2 per cent. tannic acid and 1/2000 perchloride of mercury in order to ensure that the underlying dressing is thoroughly wet. Mackintosh or jaconet should be placed under the patient until the dressing has dried in order to save soiling of the sheets by the tannic acid solution, for though this all washes out excepting for a faint iron mould, the sheet subsequently rots in this area. It is also well to secure the burnt limb temporarily in order to prevent undue movement until the tannic coagulum has formed firmly. This dressing should be left in position and untouched for at least a fortnight in the case of small burns and scalds, and three weeks where large areas are involved. At the end of this time the bandage should be cut and the dressing lifted, when the scab usually will separate completely from the burnt area. If it does not do so the dressing can be re-bandaged and removed later when separation has occurred. The separation may be rendered quite painless and assisted by spraying with tannic acid solution between the coagulum and the skin during this process. May I here say that the escape of a little serous or sanio-serous fluid from the edges of the coagulum or the raising in blisters of its centre with serum is no more an indication for interference or removal of the dressings during the first week after their application than it is with the bare coagulum resulting from the "spray" method. Temperature and toxæmia as shown by a rapid pulse, dried and furred tongue, and pain, with possibly the escape of sero-pus in considerable quantities, are the only indications calling for removal of these dressings before the time stated, and these indications in our experience are extremely rare and usually result from a failure in the thoroughness of the preliminary cleansing. Should removal be necessary, and in my experience it is very seldom called for, the area should be re-cleaned carefully and another tannic acid dressing applied.

As indicated, the dressing must be closely and evenly applied to the burnt area, and there are certain areas, therefore, such as the perineum, the groin, axillæ, the neck, and also the face, where the absence of bandages is an advantage, and where the spraying method gives better results, but the compress method has been and can be used with good effect in these areas. It must be realised that in burns where destruction of the subcutaneous and muscular tissues has occurred subsequent scarring and contracture are inevitable, and it is therefore necessary to apply tannic acid dressings, either by compresses or spraying, with the part in such a position that subsequent contracture may be counteracted. Equally is it obvious that although full epithelialisation will have occurred in those areas where the first, second, or third degree burn has occurred, an ulcer must be expected, and will be met with, in deeper burns, and this, if extensive, should be treated by subsequent autogenous skin-grafting, or if small by the application of some lotion, of which, in my experience, the most satisfactory is the following: purified alum, grs. 20; zinc sulphate, grs. 10; glycerin, 7 fluid ounces; water, to one pint.

Here I would like to draw attention to the excellence of this 2 per cent. tannic acid compress as a dressing not only for electrical, radium, and chemical burns, but also as an application to the area from which Thiersch grafts have been cut for the purpose of skin grafting in mastoid and other operations.

SOLUTION

It will be seen from the above that a stock solution of 2 per cent. tannic acid and 1/2000 perchloride of mercury will fulfil adequately the needs of the compress method. In order to meet the desirability of applying this solution warm to the burnt area it is our custom to keep it in a concentrated form and dilute it with the requisite amount of warm water. Personally I do not advise keeping it at more than double strength, as I find that more concentrated solutions are inclined to decompose more quickly, and the results obtained are therefore not so painless or so satisfactory as from the weaker solution. In order to meet the requirements of shops, or works, and the home, where burns are not frequent, or on ships, where the storage of quantities of solution is likely to be a bother, I have, with the assistance of Mr. Peck, composed a tablet containing tannic acid grs. 17½, perchloride of mercury gr. ½, and boric acid (excipient) gr. 1, which tablet dissolved in 2 oz. of water gives a solution of the necessary strength though slightly muddy in appearance, due to the presence of the boric acid which, however, does not interfere in any way with its efficacy of coagulation. It can be used equally well for spraying where this method is preferred.

Results of Tannic Acid Treatment

As will be seen from Table I., under the old bath and grease treatment, the average mortality was 39·6 per cent. burns and 18·8 per cent. scalds. In the early days of the picric acid treatment the mortality was 39·7 per cent. burns and 7 per cent. scalds, and in the last five years of the picric acid treatment the mortality was 15·5 per cent. burns and 7·5 per cent. scalds, whereas the adoption of tannic acid in October, 1928, and its systematic use in subsequent years has reduced the mortality to 4 per cent. burns and 1·7 per cent. scalds (Table IV).

If we consider the mortality in the case of children under 10 years (Table VI.), and compare them with those in the late picric acid period, it will be seen that the results with burns are not good as with scalds—a point analogous to the transition from oil to picric acid (compare Table II. and III.A). The results, however, show a distinct amelioration, and lead one to hope that further reduction in mortality may take place, and it must moreover be realised that these figures are for the severe burns alone. The Edinburgh figures (combined) for the same period are 8·7 per cent. (1926-29), 5·8 per cent. (1930), and 4·8 per cent. (1931), against St. Thomas's (combined) 3·7 per cent. (1929–'32), and Sick Children's Hospital, Toronto, 16 per cent. in 230 cases (1925–28).

I would add that during the period 1929 to the present time, when tannic acid compresses have been the routine out-patient treatment for all burns and scalds, no deaths have occurred among those slighter cases which average 800 a year, of which about one-third are in children under 10 years of age. As might be expected there is a seasonal incidence of approximately 3 : 2 in favour of the winter months. For the past three years, then, the compress method has been in use in the out-patient department at St. Thomas's Hospital with excellent results. I regret I cannot give details either of the number and type of cases treated nor of the exact degree of severity of the burns and scalds; but in only two cases has sepsis occurred of a sufficiently severe nature to call for the admission of the patients to the wards, and in both these cases cleansing and reapplication of the tannic acid dressing has led to an uneventful recovery.

TABLE VI.—*Mortality of Burns and Scalds under 10 years in St. Thomas's Hospital*

Treatment.—1924–28, picric acid 2 per cent.; 1929-32, tannic acid 2 per cent. $HgCl_2$ 1/2000.

Year.	Burns.			Scalds.		
	No.	Deaths.	Per cent.	No.	Deaths.	Per cent.
1924	7	1	14·2	23	0	0
1925	7	2	28·4	26	3	11·5
1926	7	0	0	32	3	9·3
1927	5	1	20·0	30	5	16·6
1928	6	0	0	23	3	13·0
Total 5 years..	32	4	12·5	131	14	10·4
1929	3	0	0	23	0	0
1930	3	1	33·3	34	2	5·8
1931	14	1	7·1	38	1	2·6
1932	7	1	14·2	41	0	0
Total 4 years..	27	3	11·1	136	3	2·2

I venture to think that this simple method of compress may be of universal application both by the general practitioner, in the out-patient departments of hospitals, and as a first-aid treatment in works and in the home, presenting, as it does, in its simplicity great advantages over the more complicated method of reinforced compresses recently advocated by Hunt and Scott[12] and Wilson.[9]

In the foregoing remarks I have endeavoured to trace the progress of the treatment of burns and scalds during the past 40 years, and to show that although improved social conditions and an increase in the number of scalds have done much to reduce this mortality, yet improved treatment has done more, especially the introduction, or should I say rediscovery, of the value of tannic acid in this relationship. I have described a simple method of using this tannic acid, and even if you do not consider it suitable for universal application, as I hope you may, you must admit that its success in reducing the mortality of severe burns and scalds to 4 per cent. and 1·7 per cent. respectively at least redounds to the credit of the local treatment, for social conditions remain the same as in the preceding five years when the mortality was considerably higher (15·5 per cent. and 7·5 per cent.).

Further, may I urge the necessity of separating the figures relative to the treatment of burns from those of the treatment of scalds in papers dealing with this subject.

Finally, I wish to tender my thanks, in addition to those already mentioned, to my successive house surgeons, Messrs. R. W. Butler, R. O. Lee, T. H. Wilson, R. H. Franklin, and T. W. Mimpriss, and especially to Miss Routh (sister of the septic wards), to whose patient care and continued enthusiasm much of the success of this treatment has been due.

IDIOPATHIC APLASTIC ANÆMIA

WITH AN ANALYSIS OF FOUR CASES

BY F. GRAHAM LESCHER, *M.C.*, M.D. CAMB.
PHYSICIAN TO THE DERBYSHIRE ROYAL INFIRMARY
AND
DOUGLAS HUBBLE, M.B. LOND.
ASSISTANT PHYSICIAN TO THE DERBYSHIRE HOSPITAL FOR SICK CHILDREN

APLASIA of the bone-marrow is a condition in which the hæmopoietic function of the marrow has become depressed, so that there is a diminution in the output of those blood-cells which are derived from it—i.e., the erythrocytes, the granulocytes, and the platelets.

It is not so much a disease-entity as a state produced by many conditions, such as poisoning by benzol and its derivatives; excessive exposure to irradiation; exhaustion of the bone-marrow by certain types of anæmia, such as hæmolytic anæmia and those anæmias with a megalocytic blood picture; and certain diseases which may affect the bone-marrow such as tumours and leukæmia. These conditions so depress the function of the bone-marrow that it ceases, to a greater or lesser extent, from performing its task of producing blood-cells. It is said that sepsis can produce aplasia. This and the pathogenesis of aplastic anæmia have been discussed elsewhere.[1]

But when these conditions of known ætiology have been excluded, there remains one type of aplasia, consistent in its symptoms, blood picture, and clinical history, and of no known causation, which may be regarded as a disease entity, and to which the term idiopathic aplastic anæmia is applied. It is this condition that is considered in this paper.

The symptoms and physical signs are dependent on the altered condition of the blood and they are, most commonly, pallor and shortness of breath, hæmorrhages into the skin or from the mucous membranes, and sepsis, generally of the fauces, which occurs late in the course of the disease.

This disease occurs particularly in young adults, but no age is exempt, and females are said to be more susceptible than males. It usually runs an acute course, with a fatal termination in a few weeks, but rare cases have been described in this country and in America in which the disease runs a more chronic course, and the patient is kept in reasonable health for a time by repeated blood transfusions. This type would be more accurately termed chronic hypoplastic anæmia, and the first of our cases described below belongs to it.

BLOOD EXAMINATION

The characteristic feature of the blood picture in aplastic anæmia is the great reduction of all the cells derived from the bone-marrow, together with absence of or very little evidence of erythrocytic regeneration. Dyke [2] says that the detection of a single embryonic cell in a blood film is sufficient to set aside aplastic anæmia as a diagnosis. This is not quite in accord with the experience of other observers, and certainly not with our own, but this statement emphasises the rarity of primitive red or white cells in the blood in this condition.

Although the erythrocytes may number a million or less, there is no anisocytosis and no poikilocytosis. The cells are well filled with hæmoglobin and the colour-index is generally round about or above unity.

Nucleated red cells are very rarely present, and the reticulocyte count is low, usually less than 1 per cent. Minot [3] has pointed out that transient increases even above the normal percentage may occur, and in Witts's [4] case the reticulocyte count rose on one occasion as high as 6 per cent. This is clear evidence that some normal or even hyperplastic marrow is still functioning.

The great reduction of the erythrocyte count is not due to any hæmolysis, for this is not found in aplastic anæmia, but to deficient production by the bone-marrow.

There is a marked leucopenia, but only affecting the polymorphonuclear and eosinophil cells; the lymphocytes are unaffected, and the lymphocytosis is apparent and not absolute. This reduction of granulocytes is sometimes so extreme that, late in the disease, it is impossible to detect even one polymorphonuclear cell in a blood film; if these cells are reduced below 1000 per c.mm. the resistance to infection is impaired and sepsis is likely to result.

The blood-platelets are reduced, but purpura does not result until their number is greatly diminished, usually well below 60,000 per c.mm. This marked thrombocytopenia is often seen late in the course of the disease. Whenever purpura is present, the bleeding time is prolonged and the capillary-resistance test is positive. Many authorities consider that the coagulation time is lengthened, but Minot [3] finds it normal or only slightly delayed. This author says that the fragility of the erythrocytes is abnormal, the cells beginning to break up in about the normal strength of salt solution, but that complete hæmolysis is found in a stronger solution than normal. Only in one of our cases was this test done, and in her the fragility proved to be within normal limits as tested against a control.

PATHOLOGY

The morbid anatomy of the disease is illustrated by Cases 2, 3, and 4 (vide infra). The most important negative finding is the absence of hæmosiderin in the tissues; in the occasional cases where this pigment has been reported as present, it must be attributed to hæmorrhages which have taken place, since there is no hæmolysis in idiopathic aplastic anæmia.

The positive finding of importance is the characteristic appearance of the bone-marrow, best described by Sheard.[5] The marrow cavities of the long bones are filled with yellowish-white fat, sometimes of the consistency of pus. Microscopically, all the bone-marrow cells are diminished or absent. As a rule, this fatty change is not complete, and there remain, even in the long bones, a few small scattered areas of active marrow; while it is almost customary to find that the marrow of the cancellous bones—e.g., the sternum and ribs—remains active. Owing to the defective blood-supply various internal organs will be affected with fatty degeneration.

DIFFERENTIAL DIAGNOSIS

From pernicious anæmia.—Aplastic anæmia is a disease entirely distinct in its ætiology, pathology, and symptoms from pernicious anæmia, and it is important that these two conditions should be differentiated, since the prognosis and treatment are so different. The chief points of distinction are:—

(1) The average age-incidence is higher in pernicious anæmia.

(2) Glossitis, subacute combined degeneration of the cord, and splenomegaly may be present in pernicious anæmia; these conditions do not occur in aplastic anæmia.

(3) Achlorhydria is practically always present in pernicious anæmia; this is not so in aplastic anæmia.

(4) Clinical and pathological evidence of hæmolysis is present in pernicious anæmia and absent in aplastic anæmia.

(5) The average size of the red cell is increased in pernicious anæmia and normal in aplastic anæmia.

(6) Evidence of attempted regeneration of the erythrocytes is always obtained in pernicious anæmia and is typically absent in aplastic anæmia.

(7) Aplastic anæmia does not respond when the missing hæmatinic factor of pernicious anæmia is supplied.

The distinction is not, however, always so simple as these categorical statements suggest, for it is possible to get an aplastic blood picture in pernicious anæmia when the disease is rapidly progressive; when sepsis is present; or when the disease is not under suitable treatment—i.e., when the dose of the hæmatinic factor is insufficient or the preparation used is inactive. The blood picture of these cases shows, in addition to a marked diminution in the number of the erythrocytes, granulocytes, and platelets, no sign of red cell regeneration.

The following case illustrates the difficulty when an aplastic blood picture is present in pernicious anæmia.

A man, aged 56, had suffered in February, 1931, from a severe attack of obstructive jaundice, which cleared up in a few weeks. About a month later it was noticed that he had become very pale. His blood count gave 780,000 red cells, 2400 white cells, 26 per cent. of hæmoglobin, and a colour-index of 1·6. Examination of a blood film showed no anisocytosis or polychromasia, and no nucleated red cells. Nevertheless he improved with a blood transfusion and regular doses of ventriculin, and in two months he was in good health and back at his work, taking a small dose of liver extract each day.

At autopsy an examination of the marrow in the two diseases is distinctive, though Witts [6] says that if a thorough examination of the marrow is made in any case of pernicious anæmia, areas of complete aplasia are always found. Minot [7] refers to cases in which the marrow is hyperplastic yet the blood examinations have shown evidence of aplasia. In other megaloblastic anæmias which may appear in the course of certain diseases with gastro-intestinal lesions, such as sprue, fatty and chylous diarrhœa, cœliac disease, pellagra, and infestation by certain parasites, the marrow can become exhausted and a blood picture of aplastic anæmia may result.[6]

From idiopathic purpura hæmorrhagica and agranulocytic angina.—Aplastic anæmia can usually be differentiated clinically from these two diseases. In purpura hæmorrhagica the hæmorrhages and purpura occur early, before the anæmia is evident. The anæmia is secondary to the blood loss, and signs of red cell regeneration are usually obvious in an examination of a blood film. (This is of great practical importance if the question of splenectomy arises, as one of the contra-indications is a degree of anæmia greater than would be accounted for by the hæmorrhage.) Thrombocytopenia is present in both conditions.

In agranulocytic angina signs of infection, generally in the fauces, accompanied by a profound granulopenia, occur at the onset. Characteristically there is no anæmia, and the platelets are normal in number. The diagnosis is not always easy, however; it is customary in aplastic anæmia for the hæmopoietic function of the marrow to be affected in this order: first the red cells, then the granulocytes, and lastly the platelets; but the order may be reversed, so that if the platelets fail early purpura hæmorrhagica will be simulated; but if the leucocytes are affected early, the clinical picture may resemble that of agranulocytic angina. In the second and third of our cases (vide infra) these particular difficulties in diagnosis were encountered.

Moreover, there are cases which are definitely intermediate between these three conditions, and in these it may be impossible to make a clear-cut diagnosis. Tidy[8] has drawn attention to cases of purpura hæmorrhagica in which there is evidence of some degree of aplasia of the bone-marrow with an almost complete absence of neutrophils. Minot[3] says:—

> "There are many cases in the literature which are intermediate between idiopathic aplastic anæmia with symptomatic purpura hæmorrhagica, and idiopathic purpura hæmorrhagica itself. From such cases it is suggested that these two conditions may perhaps be not distantly related, for one can find cases of these idiopathic conditions, where the blood picture can be interpreted as showing all degrees of involvement of the three chief elements of the bone-marrow."

We have suggested elsewhere[1] that these three conditions should not be regarded so much as clear-cut entities, but rather as differing stages of one disease whose cause is a primary deficiency of the bone-marrow.

From aleukæmic leukæmia.—This is a variety of leukæmia which may run part or the whole of its course without any increase in the number of leucocytes circulating in the blood stream. Aplastic anæmia is thus simulated, since the blood picture may show an anæmia, a thrombocytopenia, and a leucopenia with a relative or an absolute lymphocytosis. Clinically, fever, sepsis, and hæmorrhages may be present without obvious enlargement of the spleen and lymphatic glands. A critical survey of the blood picture should show, at some phase of the illness, a lymphocytosis, perhaps up to 90 per cent.; signs of red cell regeneration; and, even more important, lymphoblastic cells. Nevertheless, it is sometimes impossible to make a diagnosis until autopsy when, instead of the acellular marrow of aplastic anæmia, an enormous lymphocytic hyperplasia is found.

From hæmolytic anæmia.—This is a rare disease which is not likely to be mistaken for aplastic anæmia. The evidence of increased destruction of red cells in the circulating blood and an attempt at an increased formation of these cells by the bone-marrow is usually obtained without difficulty. The two clinical signs, icterus and splenomegaly, are sufficient to negative a diagnosis of aplastic anæmia, even though an aplastic blood picture develops, as it sometimes does, as a terminal event.

From severe anæmia which does not conform to any particular group.—This type of anæmia is seen more particularly in infancy. Witts[9] says that there are plastic and aplastic groups with intermediate forms of a hypoplastic type. Death may result from the complete failure of the marrow or, more often than in adults, there is a gradual resumption of function. A case reported by Hutchison[10] seems to belong to this group.

PROGNOSIS

In idiopathic aplastic anæmia the outlook depends on the degree of involvement of the bone-marrow; when much of the bone-marrow is affected, as is usually the case, the prognosis is almost hopeless, but in the rare cases of chronic hypoplastic anæmia some good may result from treatment. We have found only six reported cases of aplastic anæmia which have benefited materially by treatment; of these, two have since relapsed and died:

Stewart Harrison[11] and Parkes Weber[12] have each reported a case of chronic hypoplastic anæmia. In the former case the diagnosis was made as far back as 1925 and the patient has been treated with blood transfusions, repeated every few weeks; at present he is able to do his work and maintain moderate health. Hurst, in a personal communication five months ago, wrote that this man remained well and had just received his 144th blood transfusion. Weber's case dated from January, 1931; at the date of reporting he has had 16 blood transfusions and remained fairly well. This case proved later, at autopsy, to be one of aleukæmic myelosis (*Quart. Jour. Med.*, 1932, xxv., 409).

Herman's[13] patient was a child whose blood suggested aplastic anæmia and who improved after one blood transfusion. She died, however, of anæmia four years later, and no autopsy was obtained.

Gibson's very interesting case[14 15] was a girl, aged 11, who suffered from aplastic anæmia of an advanced type but was kept in fair health for over six years by daily injections of adrenaline. Her condition had not been improved by blood transfusion. She died of hæmorrhagic chicken-pox.

Parkinson[16] and Hayes Smith[17] have each reported a case. In both patients purpuric manifestations appeared at the onset of the illness, to be followed by anæmia. A blood film of Parkinson's patient showed some signs of erythrocytic regeneration. For these reasons it is possible that they were examples of purpura hæmorrhagica, with some temporary aplasia of the bone-marrow.

Alpham and Nelson[19] have reported a man suffering from severe aplastic anæmia, who showed no improvement after blood transfusions and treatment with calf's liver. With massive doses (1000 g. per day) of fœtal calf's liver he recovered, and kept well on a much smaller dose.

These few recoveries and remissions do little to lighten an almost hopeless prognosis.

Lately, at Prof. Tanhauser's clinic at Freiburg, a young woman was seen who developed in the later weeks of pregnancy a severe anæmia with an aplastic-like blood picture. Intensive liver therapy and repeated blood transfusions improved her condition but little. Later, after many septic teeth had been removed and without further treatment, a rapid improvement set in. In this case a diagnosis of hæmolytic anæmia was definitely ruled out, and Tanhauser's opinion was that she was a type of aplastic anæmia. Whether the removal of septic teeth contributed to the improvement it is difficult to say. Witts,[18] in his recent Goulstonian lectures, quoted Larrabee's remark that "a man's index of scepticism must indeed be low if he can believe that these terrible, acute anæmias are the result of chronic foci of infection in teeth or tonsils, and can bring himself to hope for relief from their eradication." However this may be, such cases as that quoted from Freiburg do occasionally occur. They are a reminder that, although enormous advance has been made in the last ten years in the diagnosis and classification of anæmias, clinical difficulties have not yet disappeared. It is still wise to be guarded in prognosis until the diagnosis is securely established.

TREATMENT

The success of treatment in idiopathic aplastic anæmia will depend on the degree of deficiency of the circulating blood elements, which in turn will depend on the amount of bone-marrow which remains plastic, and which is capable of stimulation. The bone-marrow stimulants which are at present known include blood transfusions, small doses of X rays applied to the long bones, foreign proteins (such as milk), and certain endocrine extracts—e.g., adrenaline. Iron, arsenic, liver therapy, and removal of septic foci are considered to be unavailing.

DESCRIPTION OF CASES

The following four cases of aplastic anæmia have been under the care of one of us in the Derbyshire Royal Infirmary.

THE FIRST CASE

A woman, aged 32, was admitted to hospital for the first time in November, 1931, with a history that she had always been healthy until about two months before, when she had noticed that she was losing energy and was becoming weak and short of breath. She had had three children; their births had been attended with no difficulty, nor had there been any great loss of blood. The periods had always been quite regular and the loss not excessive.

She was a well-nourished though very anæmic woman, but in spite of this she said that she felt fairly well. The skin and conjunctiva were pale, but there was no lemon colour of the skin and no icteric tinge of the conjunctiva. There were several infected teeth, and the tonsils were enlarged and showed some signs of chronic inflammation, though the tonsillar glands were not affected. No further sign of sepsis was found. There was no increase of temperature. No abnormality was found in the tongue, lungs, or abdominal, urinary, and endocrine organs, nor in the nervous system (with the exception of two small hæmorrhages in the left retina). Neither the spleen nor any of the lymphatic glands were felt to be enlarged. There were a few petechiæ scattered over the trunk and thighs. There was no evidence of any blood destruction. There was some dilatation of the heart, as shown by the position of the apex beat, which was 3¾ in. from the midsternal line, with a softening of the first sound.

The result of the blood examinations on various dates are shown in Table I. In addition, the red cells were found always to be of normal shape and size, and no abnormal cells or reticulocytes were seen. The bleeding time was 5½ minutes, and the coagulation time 2½ minutes (Brodie Russell). The fragility of the red cells appeared to be normal.

Pms.= Polymorphonuclears; Lms.= Lymphocytes. B.T.= Blood transfusion.

Van den Bergh's reaction was completely negative, both directly and indirectly. A fractional test-meal showed free acid in normal amounts. A series of radiograms taken at intervals after a barium meal showed no abnormal shadows in the stomach or intestines. The stools appeared normal and no ova were seen in them. One of the infected teeth was removed, but no streptococci were found on culture from it.

During the first month in hospital she was treated with iron in large doses, ventriculin, and a liver preparation both by the mouth and intramuscularly (5 c.cm. of Hepatex P.A.F. daily). As was to be expected, there was no improvement either in her general condition or in her blood, as shown by absence of increase in the hæmoglobin, erythrocytes, or reticulocytes. On Dec. 30th, after we had read an account of Gibson's successful treatment of a girl suffering from this disease, an injection of 3 minims of adrenaline 1/1000 was given, and this was continued daily for nearly a month. In six days there was an improvement in her general condition, and to some extent in her blood.

On Jan. 6th, 1932, she was transfused with a pint of citrated blood, with great improvement. This was repeated on Feb. 1st and the improvement was maintained until about the middle of the month, when she began to relapse. So, in an effort to stimulate the marrow as much as possible, three large transfusions were given at intervals of two days, and the adrenaline injections resumed daily. She was able to go home and even to do part of her daily work, but by the beginning of May more transfusions became necessary. She improved again, and arrangements were made for her to have one or two blood transfusions every month. Since then, however, the improvement has not been maintained for as long as formerly, and a transfusion is necessary about every two to three weeks. The benefit from these transfusions only lasts about two weeks, after which she quickly becomes anæmic, with extensive purpuric hæmorrhages. This patient died in July, 1932: unfortunately, no autopsy, was obtainable, so that the diagnosis in this case cannot be regarded as definitely established.

THE SECOND CASE

A boy, aged 13, was admitted into hospital on Nov. 26th, 1931, suffering from extreme anæmia. He had always been well until the last five weeks, when he had become pale, with nose-bleeding for one day just before admission. He was extremely ill, and his pallor was intense. There was no icteric staining of the conjunctivæ or skin. There were a number of petechial hæmorrhages scattered over the trunk and limbs, with some bruising of the soft tissues. A systolic murmur was heard all over the præcordium. The liver and spleen were not felt. There were no retinal hæmorrhages. The temperature was 97° F., but rose, and varied between 100° F. and 103° F. The pulse-rate kept above 140 per minute. There was no sign of sepsis. A blood examination gave the following results: 400,000 red cells, 10 per cent. hæmoglobin, a colour-index of 1·2, and 2000 white cells. The average size of the red cell was 7·48 µ (by Eve's halometer). A differential count showed polymorphonuclear cells 41 per cent. and lymphocytes 59 per cent. The erythrocytes were of normal shape but irregular in size, and a few normoblasts and megaloblasts were seen. The blood-platelets numbered 10,000 per c.mm. The bleeding time was 13 minutes, and the coagulation time 24 minutes (Brodie-Russell). With a van den Bergh's test there was a faint positive indirect reaction. The tourniquet test was definitely positive.

Soon after admission the boy was given a transfusion of 350 c.cm. of citrated blood. An injection of 3 minims of 1/1000 solution of adrenaline was ordered every four hours, and hepatex P.A.F. 5 c.cm. was injected intramuscularly once a day. On the next day the boy was decidedly better, but he collapsed the day after and died.

At the *post-mortem examination* the left femur was split open longitudinally, so as to expose the marrow of the diaphysis and epiphysis. The marrow was of a yellow-white colour, about the consistency of thick pus, with a few small scattered pink areas. That of the sternum and several of the ribs was normal in appearance.

On *microscopical examination* of the marrow from the femur no cells were seen, only fat. From that of the rib, however, red cells, both nucleated and non-nucleated, were seen, with a few granulocytes and myelocytes: no organisms were found in the marrow. There were a number of petechial hæmorrhages on the visceral layer of the pericardium. The heart was dilated. There was evidence of some bronchopneumonia (terminal) of the right lung. The liver and spleen (3 oz.) were not enlarged, and looked normal. Some of the mesenteric glands were caseous. There was a persistent thymus, but the other endocrine glands were normal macroscopically.

THE THIRD CASE

The third patient was a man aged 40, a sorter, who had always been healthy except for malaria contracted during the war, and piles which bled from time to time. About the middle of April, 1931, he began to complain of giddiness and distaste for food, with abdominal discomfort. Some degree of jaundice and pyrexia was noticed. After about ten days' treatment he improved and went back to work, only to return to his bed a few days later as the weakness had increased. On admission to hospital on May 16th he looked very ill and pale, and was in a typhoid state. The tonsils were covered with an extensive slough which had spread on to the soft palate. There was no glossitis, nor was there any sign of hæmolysis of the blood or of jaundice. Nothing abnormal was found in the chest, in the abdomen, or in the nervous system. The urine contained a trace of albumin. The temperature ranged between 99° F. and 103° F. There were no hæmorrhages into the skin or retinæ, or from the mucous membranes. A blood count on the day of admission showed 25 per cent. of hæmoglobin; 1,840,000 red cells per c.mm., and a colour-index of 0·9. The size of the blood corpuscles was 7·46 µ. There were 400 white cells per c.mm., but no granulocytes were seen; the lymphocytes numbered 88 per cent., and the large monocytes 12 per cent. No signs of attempt at red cell regeneration were to be found.

He died a short time after admission to hospital. On *autopsy* the marrow from the femora was pale and fatty; on microscopical examination no normoblasts, granulocytes, or myelocytes were to be seen, the marrow being composed entirely of fat. The marrow from the sternum and ribs, however, was normal.

THE FOURTH CASE

The patient, a man aged 44, was a clerk employed in a factory where benzol compounds were used; he was seen on Jan. 10th, 1928. His work, he said, confined him to the office only, and he had never come in contact with the chemicals. He had been quite well until about six weeks before, when he noticed that he was becoming weak and breathless. He had been told that he was becoming pale.

On examination he looked a well-nourished man, but showed marked pallor. There were no enlarged glands, and the spleen and liver appeared normal. Nothing wrong was detected in his chest or abdomen except some dilatation of his heart. There was no sign of sepsis. He had some oozing of blood from his gums, but there was no clinical sign of blood destruction.

TABLE II

Date.	Hb. per cent.	Red cells per c.mm.	White cells per c.mm.	Granulocytes per cent.	Lymphocytes per cent.
Jan. 10th	35	1,500,000	4,400	11	89
„ 11th	30	1,090,560	1,600	41	58
„ 12th	20	860,000	400	8	92

A series of blood examinations is shown in Table II. There was no sign of any attempt at erythrocytic regeneration. On *autopsy* the marrow of both femora was examined, and practically all the hæmopoietic tissue was found to be replaced by fat. Microscopically no cells were seen except a few mononuclear ones.

COMMENTARY

The first of these cases is the most interesting, and undoubtedly belongs to the group named chronic hypoplastic anæmia, of which very few examples have been reported. The possible alternative diagnoses are pernicious anæmia with an aplastic blood picture, and lymphatic leukæmia in an aleukæmic phase. The diagnosis of pernicious anæmia is easily dismissed by the absence of the necessary clinical and pathological criteria, and by the steady clinical and hæmatological deterioration under intensive liver therapy.

The diagnosis of aleukæmic leukæmia deserves more serious consideration, for in a few of the differential white cell counts there is a slight but absolute lymphocytosis; in one instance only, however, did these cells number over 3000 per c.mm., and that was a few days after injections of adrenaline had been started (adrenaline produces a transient lymphocytosis). Against the diagnosis of leukæmia is the absence of embryonic types of lymphocyte and of any sign of red cell regeneration; and the fact that, although the case has been under observation for some months, no enlarged lymphatic glands have been detected. Although this diagnosis cannot be dogmatically dismissed, yet the patient's reaction to blood transfusions and adrenaline injections suggest that the diagnosis of chronic hypoplastic anæmia is likely to be the correct one. An interesting observation in this case was that there were no purpuric manifestations until the platelet count had fallen to 30,000 per c.mm.

In the second case the blood loss was not sufficient to cause the grossly anæmic blood picture, and the fact that the child had been ill and noticeably anæmic for many days before hæmorrhages or purpura were observed establishes the differential diagnosis from purpura hæmorrhagica. There were a few signs of attempted blood regeneration, but it should be remembered that in children the bone-marrow is more labile than in adults; moreover, some signs of red cell regeneration do not rule out aplastic anæmia. Cabot[2] has reported a man suffering from aplastic anæmia, whose blood film showed marked evidence of regeneration, but on autopsy typical aplasia of the marrow was seen. Acute leukæmia was a possible diagnosis during life, but this was definitely excluded by the post-mortem examination. There was no clinical sign of hæmolysis, and no hæmosiderosis was seen at autopsy, yet the van den Bergh's test showed a slight positive indirect reaction (probably this is without diagnostic value), so that it is possible, but unlikely, that this was an example of the acute hæmolytic anæmia in children which terminates in aplasia, and which has been described by Kleinschmidt (quoted by Minot[3]).

In Case 3 the gross leucopenia with complete absence of granulocytes, and the predominant picture of infection and fever, suggest a diagnosis of agranulocytic angina; but the severe anæmia and the aplasia of the bone-marrow at autopsy place it in an intermediate group between aplastic anæmia and agranulocytic angina. A platelet count might have confirmed this, but unfortunately it was not done; it is significant, however, that this was the only case in our series to be without purpura or hæmorrhages, and it was also the only case to show evidence of sepsis; but in others there was not such an extreme granulopenia, except terminally in Case 4.

The morbid anatomy of the bone-marrow in the cases that came to autopsy conformed to the classical descriptions.[5] In the two adults the whole of the femoral marrow showed the typical yellow appearance of complete aplasia, but in the child there were a few isolated pink areas with a small cell content. The marrow from the sternum in all three cases appeared normal both to the naked eye and microscopically. Dyke[21] has reported various kinds of micro-organisms in the bone-marrow in cases of aplastic anæmia, but careful search failed to reveal them in our cases.

Our thanks are due to Dr. Hugh Barber for his kindly help and criticism in the preparation of this paper, and to the staff of the pathological department of the Derbyshire Royal Infirmary for undertaking all the blood examinations.

DONATIONS AND BEQUESTS.—The late Mr. Charles Wilson, of Belsize Park-gardens, London, left £500 to the Paddington Green Children's Hospital, and the residue of the property after other bequests between St. Thomas's Hospital, London Hospital, Charing Cross Hospital, the Hospital for Sick Children, Great Ormond-street, the Royal Free Hospital, the Cancer Hospital, Fulham-road, the London Fever Hospital, the Temperance Hospital, Hampstead-road, and the Hampstead General Hospital. The value of the estate is over £200,000.—Mrs. Martha Jones, of Edgbaston, left by will £500 to the General Hospital, Birmingham; £500 to Queen's Hospital, Birmingham; £500 to the Children's Hospital, Birmingham (King Edward VII. Memorial); £500 to the Birmingham and Midland Eye Hospital; £100 to the Midland Hospital for Homœopathic and General Treatment, Birmingham; £100 to the Birmingham and Midland Hospital for Women; £100 to the Birmingham and Midland Skin and Urinary Hospital; and £100 to Dr. Barnardo's Homes.—By the will of the late Mr. William Lyle, of Welwyn, Herts, the Hertford Cottage Hospital will receive £5000, the Hertford and District Nursing Association £1000, and the Welwyn Cottage Hospital £500.

A NEW FORM OF BED TENT FOR ADMINISTERING OXYGEN AND CARBON DIOXIDE

By E. P. POULTON, D.M. OXF., F.R.C.P. LOND.
PHYSICIAN TO GUY'S HOSPITAL

With an Account of a
CLINICAL OXYGEN-MEASURING PIPETTE, *by*

E. P. POULTON *and* J. W. SHACKLE, M.R.C.S. ENG.

MANY methods have been employed for administering oxygen, but none of them is altogether satisfactory.

The *nasal catheter* has the advantage of simplicity, and it does not unduly inconvenience the patient; it was used first by the late Prof. Adrian Stokes of Guy's Hospital during the war, and it is the method most widely employed to-day. The proportion of oxygen in the alveolar air is raised to 24 per cent. with the oxygen flowing at 2 litres a minute; this means a brisk turbulent flow in the bottle through which the gas is usually bubbled; 24 per cent. is less than twice the normal value, so that the method cannot be regarded as really effective.

Higher values for the alveolar oxygen may be obtained by using a *face mask* as in Haldane's apparatus, or the various modifications described by H. W. Davies and A. R. Gilchrist,[1] and by R. Hilton[2]; but breathless patients are apt to resent all these devices, and the face mask is usually refused altogether. Hence it is not surprising that other more tolerable methods of giving oxygen have been elaborated, such as the oxygen chamber and the bed tent provide.

The discredited *glass funnel* that is still often supplied by chemists when oxygen is ordered was found by Hilton to cause no increase whatever in the alveolar oxygen at any rate of flow when held 10 cm. (4 in.) in front of the mouth; but when held so as to touch the nose and chin it has, with an oxygen flow of 2 litres a minute, a rather smaller effect than the nasal catheter.

Whenever oxygen therapy is discussed the question of *subcutaneous oxygen* is usually raised. If the results are beneficial they may be due to counter-irritation or acupuncture; but they certainly cannot be due to the oxygen acting as a respiratory gas, for Davies and Rabinovich[3] produced anoxæmia in dogs from pulmonary embolism; the oxygen saturation of the arterial blood was made normal by giving oxygen through the lungs; but there was no effect with subcutaneous and intraperitoneal oxygen.

HISTORY OF OXYGEN CHAMBERS AND TENTS

The first oxygen chamber was used at Cambridge during and after the war, and results with patients were published by Barcroft, Hunt, and Dufton.[4] There are oxygen chambers at several clinics in America, and A. L. Barach has devised a portable chamber. The experiences with the oxygen chamber which was in use for some years at Guy's Hospital were briefly described by Campbell and myself.[5] It was a large chamber with three beds, and it required 600 cubic feet of oxygen to begin with, and later from 300 to 600 cubic feet every 12 hours, as well as alkali to absorb the CO_2.

It is clear that the stationary oxygen chamber will never be of general clinical application, and the oxygen bed tent has most of its virtues and none of its failings. The object of the tent is to enable the patient to stay any length of time in an atmosphere enriched to any desired extent with oxygen, and containing CO_2 as well if required; the heat generated by the patient must be removed, and also the moisture from his breath amounting to as much as 10 oz. in the 24 hours.

The first bed tent was devised by Sir Leonard Hill.[6] Its disadvantage was that there was no adequate means of keeping the patient cool: but it was provided with a motor fan in an outer circuit to draw the air from the tent and pass it through a tin of soda lime and back again to the tent. The next advance was made by Barach,[7] who added a box to the circuit large enough to hold over 100 lb. of ice, and this has to be replenished every 12 hours: the shape of tent and "sleeve" described by him are now generally adopted. The next great advance was made by Cecil and Plummer [8] who introduced the injector, which replaced the motor fan in the circuit. In the injector the oxygen comes out under pressure through a minute orifice into the circuit, and the energy liberated is used to draw air round the circuit, so that the ventilation is effected by the potential energy of the oxygen stored in the cylinder: thus the working of the tent is independent of an electrical supply.

THE AUTHOR'S TENT *

In my experience the greatest difficulty in treating a patient by means of an oxygen tent is to keep him dry and cool. In the plan adopted by Barach and by Cecil and Plummer a high rate of ventilation is required for this purpose, though a much lower rate is sufficient to remove the CO_2. In the Cecil-Plummer apparatus a ventilation of 175 litres of air is used, and this requires an oxygen feed of 5 litres a minute, which produces an atmosphere containing about 50 per cent. of oxygen, and yet if the tent is reasonably air-tight I have found that from 1 to 2 litres of oxygen a minute is enough to keep the oxygen up to this amount. By keeping the mechanism for cooling and drying separate from the CO_2 absorption circuit a great saving of oxygen is effected.

FIG. 1

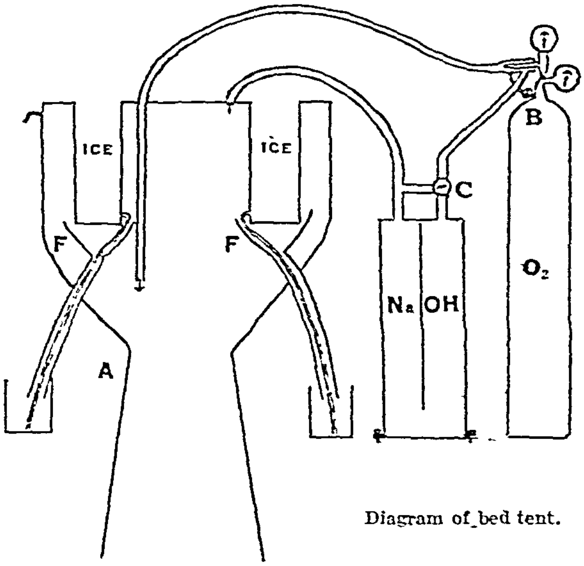

Diagram of bed tent.

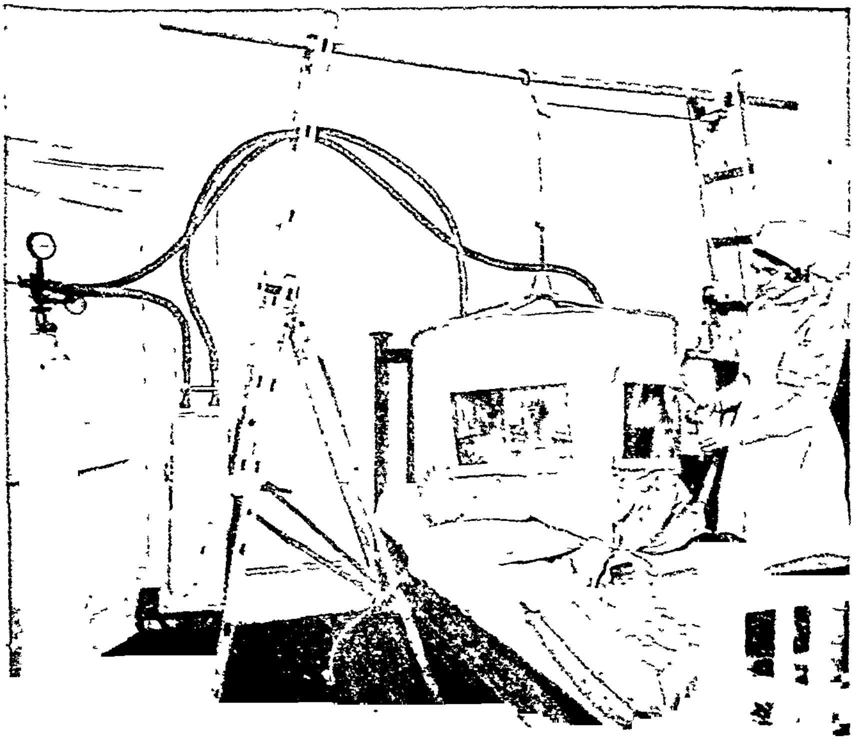
The mechanism consists of two tins with radiating fins which are let in through the roof of the tent and fixed in position by bolts which can be removed at will. The tins are filled with lumps of ice or ice and salt in layers, so that the air inside the tent is cooled, and the moisture from the patient condenses on the surface and on the fins of the two tins, and runs off down the funnels (Fig. 1, F) to be collected outside the tent. As the ice melts the water can be run off by means of a thin rubber tube, which is threaded through the wider tube from the funnels. As a mixture of ice and water is of the same temperature as melting ice it is an obvious economy of ice to wait until most of it is melted before running off the water. As little as 36 lb. of ice has been required in the 24 hours, which costs less than 1*s.* 6*d.* at wholesale prices. Both tubes can be controlled by a single clip outside the tent: but as the inner tube from the ice tin is longer than the outer tube the flow of water from the ice tin can be controlled separately by a clip, and in this case it is essential that the end of the wide tube should lie beneath water, or otherwise there will be a leak from the tent through the funnel to the outside air. The funnels are made of the same waterproof fabric as the tent, and are suspended from the roof by means of fine chains.

FIG. 2



The portable bed tent in use. The nurse is taking a sample for oxygen analysis.

If ice alone is used in rather big lumps, the dry bulb thermometer usually remains about 65° F., and the relative humidity deduced from the wet bulb reading varies between 50 per cent. and 70 per cent.[9] The cooling power on

---

* The tent is being marketed by Messrs. Siebe Gorman and Co., Ltd., 187, Westminster Bridge-road, London, S.E. 1. Inquiries from the midlands should be made to Mr. J. Muirhead, 11, Cannon Hill-road, Birmingham.

April 29th, 1932, as determined by Hill's kata-thermometer, was 5·8 with a dry bulb of 66° F., and a humidity of 59 per cent.; while on May 5th it was also 5·8, with a humidity of 69 per cent. Since for comfort the cooling power should not be below 6 in summer or 5 in winter, the cooling power in the tent is reasonable, though it might perhaps be increased with advantage by increasing the radiating power of the tins, though care would have to be taken to prevent the temperature inside the tent from falling too low; further observations are being made on this point.

The tent itself (Fig. 2) is provided with two large celluloid windows in front and two behind. The "sleeve" through which food and drink, &c., are passed is placed towards the front beneath the windows, and below the latter there is, in the more recent model, a piece of rubber tube passing into the tent which can be clipped on the inside; this is to give confidence to the patient, who, if he wished, could take off the clip and breathe through the tube into the outside air; it might also be used for "tube feeding." Dry and wet bulb thermometers (Mason's hygrometer) can be suspended from the roof of the tent, and a piece of lead tubing of very fine bore passes into the tent at the side through which samples of air in the tent are obtained for analysis.

The modified Cecil-Plummer injector which Mr. R. W. G. Davis suggested and has made for me is screwed into the top of a 100-cubic foot oxygen cylinder. From this injector two rubber tubes lead one through the roof towards the bottom of the tent, and the other to the CO_2 absorption box; another tube connects the CO_2 absorption box with the tent, the whole forming a closed circuit. The injector supplies oxygen to the circuit, and at the same time circulates the air from the tent through the CO_2 absorption box and round again to the tent. The rate of supply of oxygen with the corresponding rate at which air is being driven round the circuit is shown by the dial at the top of the injector; it can be varied by turning a handle—this is a new feature. The lower dial shows the pressure of oxygen in the cylinder. The injector is also provided with a by-pass by which the oxygen can be made to pass directly into the circuit without passing through the injector, so that at the beginning of treatment the percentage of oxygen is quickly raised. The by-pass is then turned off, and the injector set to deliver the required amount of oxygen.

It is never necessary to deliver more than 3 litres of oxygen a minute, and 2 or even 1 or 1½ litres a minute are often sufficient to keep up the desired percentage. The economy in oxygen depends on the tent being as air-tight as possible, and to effect this the lower part of the tent should be wrapped closely round the patient's abdomen and kept tight by means of a rubber or elastic bandage at A. One garment at most should intervene between the body and the tent where it is fixed by the belt; the rest of the clothes covering the body are pushed right up into the tent, and the lower part of the body is covered with pyjama trousers and bed-clothes. The extra length of the tent below A is for children who can be pushed right up into it and the opening tied with a piece of bandage. When adults are treated this part of the tent is folded up—hence its shape.

The CO_2 absorption box is filled in the upside down position after unscrewing its base. A very efficient mixture to use for absorption is alternate layers of soda lime and flaked caustic soda; the caustic soda is mainly responsible for the absorption, while the soda lime keeps the layers of caustic soda apart and so prevents the flakes from becoming stuck together in lumps. With this mixture it is found that one filling of the tin lasts during several days of continuous use. In my experience soda lime by itself soon becomes exhausted. Messrs. Siebe Gorman supply fused caustic soda on coke, which is also effective; but the tin gets much hotter than with the above mixture. The same firm provides soda lime tinted light green, which turns brown when it becomes exhausted. A window can be provided at the top of the tin near the exit tube, and if a little of this tinted soda lime is poured in first of all some indication may be given when the absorption is giving out; however, so far I have not tried this in practice, but have relied on analysis of the air of the tent for CO_2.

Any percentage of CO_2 can be used in the tent by altering the by-pass on the CO_2 absorption box (C) so that the air flows partly through the box and partly through the by-pass. It is probably the case that CO_2 is just as important or more important than O_2 in some conditions—e.g., CO poisoning—but our knowledge of its value in pneumonia is still scanty. A very good percentage to try is 40 per cent. of O_2 and 2–3 per cent. of CO_2. The correct position of the by-pass tap can only be obtained by experimenting. The tap should be arranged in the half-way position in the first place, and after five or ten minutes the CO_2 in the tent is determined and further adjustment of the tap made.

Owing to the nature of the cooling and drying arrangements the present oxygen tent is a good deal heavier than those previously described, and it is essential to have a substantial supporting structure. Two patterns have been made. The one shown in Fig. 2 is the portable apparatus; the extension ladders withdraw into a length of 5 ft., and the bar unscrews into two pieces so as to fit on to the luggage carrier of a car. The ice tins are removed, the tent folds up flat round its roof, and can be re-erected anywhere in less than half an hour. But for hospital work a movable trolley which will take the oxygen cylinder and CO_2 absorption box and at the same time suspend the tent over a bed would be of undoubted convenience. A trolley is at present in use at Guy's Hospital; but its final form is not yet complete.

When in use the tent requires more or less continuous supervision, at any rate until the nurse is thoroughly familiar with it. The ice tins must be kept filled, and the rate of flow of the oxygen observed from time to time. It is essential to be able to determine the composition of the air in the tent periodically—e.g., at hourly intervals—and this is of special importance if CO_2 is being employed. Two pieces of apparatus † have been devised by means of which sufficiently accurate determinations of the O_2 and CO_2 can be made by a nurse after two or three minutes' instruction. The "clinical oxygen-measuring pipette" is described by Shackle and the author in an accompanying note. The dry bulb thermometer should read about 65° F., and the wet bulb should read at least 8° F. lower. No matches or cigarettes or electrical appliances—e.g., heating pads—are allowed in the tent, and lamps and naked flames must be kept well away from it. Several disasters have been reported elsewhere from neglect of these precautions.

Emphasis has been laid on the tent being air-tight, so as to economise oxygen. No attempt is made to secure this in the American patterns, and Barach [7] has argued that a leak may be of value to ensure the replacement of the rare gases of the atmosphere which may act like vitamins, and may be used up by the patient—both highly speculative propositions as he admits. It is difficult to follow the argument. Some leakage of air into the tent may take place when the sleeve is open in all patterns of tent; but when the tent is closed up the leak will be entirely outwards, and a brisk flow of oxygen will the more quickly drive out the air originally in the tent with its rare gases. Therefore the smaller the leak the more will the rare gases be conserved, because the oxygen formed by electrolysis presumably contains even smaller traces of rare gases than atmospheric air does owing to their slight solubility in water.

INDICATIONS

So far the tent has been used for some 30 patients at Guy's Hospital and Lewisham Hospital. The results are not yet numerous enough for analysis;

---

† Demonstrated at the International Physiological Congress, Boston, 1929.

but a few instances of its value in the treatment of pneumonia may be given.

A man, aged 67, with untreated diabetes of several years' duration was admitted to Guy's Hospital on Feb. 16th, 1932, with hypostatic pneumonia and bronchitis. The prognosis was grave. He remained in the tent from 7 P.M. till 10 A.M. the next morning; he was much better, and eventually went out with lungs pretty clear of physical signs.

A baby aged 2, admitted to Guy's Hospital on June 8th, 1932, was very ill with pneumonia. Prognosis almost hopeless. She was put in the tent intermittently for 228 hours; each time she was put in the temperature went down to normal, rising again when she was taken out; she made a complete recovery.

A boy, aged 7, was admitted to Lewisham Hospital on June 2nd, 1932. He was considered "moribund" by the medical officer, and was too ill to protest at being put in the tent at 11 A.M.; at 5 P.M. he had recovered sufficiently to want to come out; he was kept in till 8 A.M. the next day, and on the two following nights for 14 and 15 hours respectively; he made a complete recovery.

I have some evidence that a mixture of CO_2 and O_2 in the tent may be of value in frequently occurring attacks of asthma; but more observations are required.

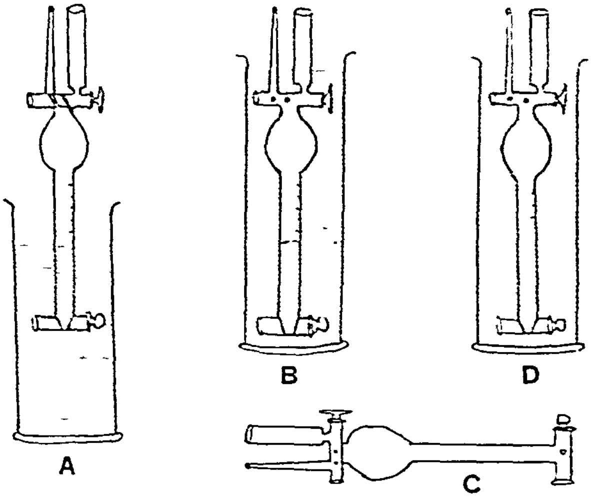
There is already a fairly extensive literature on treatment with oxygen chambers and oxygen tents. Good results, tested during and after muscular work by observations on the respiratory exchange, &c., were obtained by J. M. H. Campbell and myself for chronic bronchitis, emphysema, and myocardial degeneration[5]; we suggested that the same principle was involved in this treatment as in treatment by compressed air which was initiated years ago at the Brompton Hospital. Binger[10] has treated pneumonia patients, and Barach,[11] dealing with 100 patients, claims beneficial results; one patient lived in a tent for two months, which appeared to prolong his life until he had developed immunological resistance to the disease. Barach and Richards[13] obtained good results in congestive cardiac failure, a finding that I can confirm in two cases. Barach[12] has also found that the cardiac pain due to coronary sclerosis was relieved; a patient of mine with frequent attacks of angina found she was better in the tent.

This by no means exhausts the indications for treatment. Since a tent is merely an efficient means of giving oxygen with or without CO_2, it should be valuable in carbon monoxide poisoning, shock, post-anæsthetic pneumonia, methæmoglobinæmia, &c.

DIAGNOSIS

By this is meant the problem of determining when oxygen should be given. It is not a very simple one because, though every one would admit that oxygen should be given when there is arterial desaturation (anoxic cyanosis), there may be conditions when it may be of value even though the arterial saturation is normal. For instance, the heart's action may be so defective that the coronary circulation is slowed, and the muscle is deprived of its normal supply of oxygen, though the local increase of CO_2 will enable it to get a larger proportion than normal out of the circulating blood. By giving oxygen this state of affairs may be remedied not so much by the comparatively small extra volume that will be taken up by the arterial blood as by the very much higher partial pressure it will exert. Again, observations by J. M. H. Campbell, G. H. Hunt and myself[14] showed that while decided cyanosis always meant arterial desaturation, the reverse was not always true. In some cases of arterial desaturation there was no cyanosis. Cyanosis is largely a question of peripheral stasis in the parts observed—lips, cheeks, ears, finger-nails, &c. The conclusion is that in all cases of temporary cyanosis oxygen should probably be given; congenital heart disease and polycythæmia are rightly excluded on this definition. But in all cases of breathlessness the administration of oxygen should at least be considered, excluding of course the breathlessness of diabetes and uræmia. When in doubt its effect should be tested, and the best way to do this is to give pure oxygen, using the face mask and large rubber bag that every doctor possesses for giving nitrous oxide gas. If oxygen is given for five or ten minutes in this way the patient will be able to tell if relief is experienced and any improvement in colour may be noticed by the doctor and then a more practicable method of administration may be chosen, and among them the oxygen bed tent should at least be considered.

FIG. 3



A clinical CO_2-measuring pipette.

This work was begun under the auspices of the "Clinical Uses of Oxygen" Committee of the Medical Research Council, and the expenses have been defrayed by grants from the Council, to whom my best thanks are due. I should like to thank the sisters and nursing staff of Guy's Hospital and Lewisham Hospital for their willing coöperation and hard work, and the same applies to many of my ward clerks. I wish to thank Mr. A. E. Gould for his help in making the apparatus.

A CLINICAL CO_2-MEASURING PIPETTE

This pipette, shown in Fig. 3, is a modification of Fridericia's alveolar CO_2 tensimeter.

It is filled with water by placing it in a cylinder of water; both taps are open as at A. The top tap is then closed and the nozzle of the pipette is connected to the sampling tube of the tent. The pipette is lifted approximately half way out of the water in the cylinder. On turning the top tap the water runs down in the pipette as far as the level of the water in the cylinder drawing air from the tent *after* it, as shown at A. It is not necessary to take in any exact quantity of air. The top tap is then closed, the apparatus disconnected and lowered again in the cylinder, and left for two or three minutes to equalise the temperature, as shown at B. The volume of air in the pipette is read at the lower level of the meniscus, while the pipette is standing upright in the cylinder. Then the pipette is raised half way out of the cylinder; the funnel is filled with 15 per cent. caustic soda, which is allowed to run slowly into the pipette. The pipette is then further raised from the cylinder and the lower tap closed: the pipette is taken out of the cylinder and turned up and down several times, as at C. The CO_2 is absorbed by this means. Care is taken to see that the space below the lower tap is filled with water before the tap is opened beneath the surface of the water, and the pipette is again lowered into the cylinder. After a few minutes to equalise the temperature, the level of water is read again, as at D; the difference between the two readings, without any further calculation, gives the percentage of CO_2 in the atmosphere of the tent. Since the pipette down to the zero mark in the middle of the stem has a volume of 20 c.cm., and the stem is graduated in 10ths of a c.cm., each division will correspond to a 0·5 per cent. CO_2. After the determination has been made, rinse through with some water and then with some 1 per cent. sulphuric acid solution to get rid of the alkali.

CONCLUSIONS

An "oxygen bed tent" is described with the following new features: (1) Cooling and drying are effected by means of ice tins let in through the roof of the tent. (2) Ventilation is produced by means of an injector as described by Cecil and Plummer; but the stream of oxygen with the ventilation can be varied. (3) CO_2 is administered by partially short circuiting the CO_2 absorption box. (4) A clinical CO_2-measuring pipette is described.

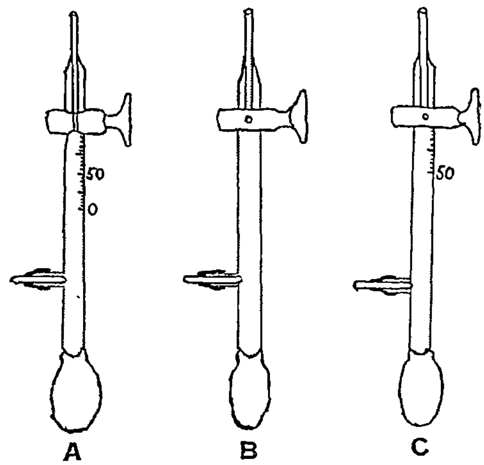
A CLINICAL OXYGEN-MEASURING PIPETTE

By E. P. Poulton and J. W. Shackle

The top cubic centimetre of the pipette (Fig. 4) is graduated in percentages; the diameter of the tube is chosen so that the zero mark reaches to about 4 cm. below the tap. The rubber bulb has a capacity of ½ oz.

Fig. 4



A clinical O_2-measuring pipette

The pipette is filled with a mixture of pyrogallic acid in caustic potash made up as follows: 70 g. of caustic potash in sticks is dissolved in 100 c.cm. water; to this mixture (i.e., 100 c.cm.) is added 20 g. pyrogallic acid. The side tube attached to the lower end of the pipette contains a projecting piece of glass rod fixed to the side tube by a piece of rubber tubing, so that the glass rod can slide backwards and forwards inside the tube. With the tap open, the level of the pyrogallic acid is adjusted to the zero mark by altering the position of the glass rod, as at A. The rubber bulb is squeezed so that the pyrogallic acid runs just above the tap, which is then turned (B).

The nozzle of the pipette is attached to the sampling tube of the tent and the tap opened for one second and then closed. The pipette is then disconnected from the tent and turned up and down until the air bubble ceases to contract. The height to which the level of the pyrogallic acid rises above the zero mark in the pipette gives the percentage of oxygen in the tent. In C this is seen to be 40 per cent. It is better not to allow the bubble to pass into the rubber bulb, as there may be difficulty in getting it back again; to prevent this the pipette can be fixed in a stand which keeps the tap on a higher level than the bulb. This is important because when not in use there should always be about a cubic centimetre of gas in the pipette, and the tap should be closed; if the pipette is always kept in position B the tension-length curve of the rubber bulb becomes altered, so that in a determination less than 1 c.cm. will be sucked into the pipette, and there will be an error in the final reading. The accuracy was within 5 per cent., when tested against a Haldane gas analysis apparatus; this is sufficient for the purpose. The following percentage figures were obtained by J. W. S. (Haldane values in italics): gas mixture A: 57, 55, 56; *54·1*. B: 62, 63, 64; *65·6*. C: 73, 88, 88, 81; *87*.

Clinical and Laboratory Notes

AN EASY METHOD OF DEMONSTRATING SOME OF THE VIRUS BODIES

By Alfred C. Coles, M.D., D.Sc., M.R.C.P. Lond., F.R.S. Edin.

PHYSICIAN TO ROYAL NATIONAL SANATORIUM; CONSULTING PHYSICIAN TO ROYAL VICTORIA HOSPITAL, BOURNEMOUTH

It is now generally, but not universally, thought that virus bodies are living organisms distinguishable from bacteria only by their small size, and, as Prof. J. C. G. Ledingham says, it is a "recently ascertained fact that there exists a group of viruses—variola, vaccinia, fowl-pox, ectromelia, molluscum contagiosum, &c.—whose individual elements are just big enough to be detectable by appropriate staining methods."

The usual method of staining is to fix the air-dried films in absolute alcohol and subject them to long staining with Giemsa, say for 12 to 48 hours, preferably changing the Giemsa two or three times. Incidentally, I may mention that for the last 20 years I have used industrial methylated spirit both for fixing and making up the stains instead of absolute alcohol. It is sometimes advisable to soak the air-dried films in normal saline, Ringer's solution, or even distilled water for ten minutes or so, in order to remove the layer of serum surrounding the bodies and so facilitate the staining; the films are then fixed in alcohol and stained in the usual way. Other methods are first to treat the films with hot Loeffler's mordant and subsequently stain them in gentian or methyl-violet or carbol-fuchsin, as in the process of flagella staining. Personally I prefer the use of Giemsa.

For some time past I have demonstrated these small bodies by simply mixing a drop of the material containing the virus with a drop of Indian ink and spreading a thin film as in Burri's method. Preparations made as suggested can be examined with the highest powers of the microscope, either by ordinary or by dark-field illumination.

A method I have adopted for some years is to examine, under dark-ground illumination, air dried, unfixed, unstained, and unmounted smears made on a cover-glass or slide. This very simple and rapid process shows the elementary or virus bodies in many cases exceedingly brilliantly. The method I use is as follows:—

A film of the material containing these bodies is spread not too thinly on a scrupulously clean slide or cover-glass Allow the smear to dry thoroughly in the air. Examine this smear by any form of dark ground illumination with an objective whose N.A. does not exceed 0·65 I use a ⅓ inch or 8 mm. apo. objective of N A. 0·65, and obtain a dark ground by merely turning in an expanding stop below the condenser which is always on the microscope for general use—viz , Watson's parachromatic

If the air dried film on the slide be examined without a cover-glass then the tube length of the microscope must be lengthened, this in the case of the Leitz 8 mm. is from the normal tube length of 170 to about 210 mm.; in the Zeiss 8 mm. from 160 to about 185 mm. in order to correct for the absence of a cover. When the correct tube length of a given objective on an uncovered film is once determined it is constant for that objective on any smear notwithstanding the thickness of the slide, whilst the tube length of an object glass varies with the varying thickness of any cover-glass. If, however, a cover-glass is laid on the film on the slide, or if the cover-glass preparation is laid smear downwards on a clean slide, and kept in position by a little plasticine or a spot of melted paraffin, the tube length of the microscope will need very little alteration from that of the normal. Lenses are very sensitive to tube length, especially on dark fields

Of course the ordinary oil-immersion dark-ground illuminators on the market, when oiled to the slide in the usual way, will give a very bright dark ground, but the simpler method of using a stop of suitable size at the back of an ordinary dry condenser gives a very brilliant image with the ordinary paraffin lamp. The usual ⅙ inch objective found on most medical microscopes can be used if its N.A. is not over 0·65, or it can easily be stopped down to that amount by a funnel or stop behind the back lens, but even then it can only be used when there is a cover-glass on the film, as it will not work through an uncovered film.

The 8 mm. or ⅓ inch objective can be used with any eye-piece from No. 0 to the compensating ocular 18, and I find that either the ordinary No. 4 or the compensating ocular 6 or 8 gives excellent results

As a matter of fact I can see the virus bodies of molluscum contagiosum well with even a common ⅔ inch of N A. 0·25 (costing pre-war, 15*s.*) with any of the higher eye-pieces. I have also taken some photomicrographs of these bodies on an old air-dried smear on the slide made three years ago, with an apo ⅔ inch or 16 mm. of N.A. 0·30 and a compensating ocular 8 giving a camera magnification of 160 diameters. In these photographs the virus bodies come out very sharply

Films made on slides have many advantages over those made on a cover glass They are much more easily manipulated, and films of control material may be made by the side of the infected material and so they can be compared; further, if these films are uncovered the position of the best colony of virus bodies, which are often in almost pure cultures, can be marked with a diamond marker and their position logged. Then the slide may be removed, fixed in alcohol, and stained in Giemsa, and the marked organisms can be examined under the 1/12 objective in the usual way.

Permanent preparations can be made from air-dried unstained films by painting round the margins of the cover-glass a ring of melted paraffin and then subsequently a layer of any of the usual cements.

By the above simple method I have been able to examine many of the elementary or virus bodies, among others those of vaccinia, varicella, herpes labialis and zoster, pemphigus, and molluscum contagiosum.* It only takes two to five minutes from the time the smear is made.

When examined in this way the virus bodies in the dry unstained condition appear as distinct sharply defined bright round or oval bodies, singly, in pairs, or in dumb-bell forms, and in short chains, and when experience has been acquired they cannot easily be mistaken, especially when a colony in pure culture is found. So far as I know at present, there is only one possible fallacy; that is, the surface of some glass slides and cover-slips are covered with innumerable roundish minute bodies which on a dark field might be confused with the viruses. This condition cannot be removed by any method of cleaning, and I obviate this by examining the clean slides by dark-ground illumination before spreading the film, and so eliminate any doubtful slides

Unfortunately I am only able to obtain specimens of the commoner virus diseases, and I should be grateful if some of the workers on these small organisms would kindly spare me any unstained films, or any stained films showing some of the inclusion bodies characteristic of many of these diseases.

TWISTED OVARIAN CYST WITH ABSENCE OF THE UTERUS

By N. J. Nicholson, M.B. Edin.
HOUSE SURGEON, LEICESTER ROYAL INFIRMARY

A woman, aged 27, was admitted to the Leicester Royal Infirmary on Sept. 29th, 1932. Violent pain had begun in the right iliac fossa that afternoon, and she had vomited afterwards. The bowels were open satisfactorily, but there had been some pain during micturition on that day. She said she had never menstruated.

She was a pale, thin woman. her tongue was in fair condition, and there was tenderness and rigidity in the right iliac fossa It was noticed that pubic hairs were absent, but there were sparse hairs on the labia. The vulva appeared normal. The vagina admitted one finger. The top of the vagina felt dome-like, and no cervix could be palpated. The finger felt a rounded swelling in the pelvis not palpable through the abdomen. There was tenderness to the right on rectal examination. Her temperature was 98·2° F., her pulse-rate 96, and her respiration rate 24.

The patient had a general anæsthetic, and a right paramedian incision was made. A full bladder presented, and a glass catheter was passed. Behind the bladder in the pelvis lay a dark red mass. The upper abdomen was packed off, the patient having been placed in the Trendelenburg position. The mass was brought out of the pelvis; it was roughly spherical, and rather larger than a cricket-ball. It had a pedicle attached to the right side of the pelvis, and the pedicle was twisted two and a half times in a clockwise direction. The twists were undone, the pedicle was clamped and ligatured, and the cyst was removed. Thereafter a better view of the pelvis was obtained. The left ovary was healthy, except for one or two retention cysts in process of extrusion. Associated with it was a structure 1½ in long, apparently tubal; it had a fimbriated infundibulum, but the ampulla tapered away medially into the floor of the pelvis and ended about 1½ in. from its ostium. The floor of the pelvis was smooth except for a wrinkle of peritoneum, running from side to side, uniform in thickness There was nothing suggestive of a rudimentary uterus. On the right side of the pelvis was the pedicle of the cyst which had been removed, corresponding in position to the ovary and tube of the opposite side. The rectum and bladder were healthy. The stump of the pedicle was peritonised, the cysts were removed from the left ovary, the appendix was removed, and the abdomen closed.

This patient has three brothers and four sisters. The sisters menstruate naturally. None of her brothers or sisters have any deformities The patient herself has had no vicarious menstruation or molimina. Her breasts began to enlarge when she was 16; no enlargement of thyroid or parotid was noticed then. Her breasts were of average size, but the nipples pale and undeveloped. There were no hairs in the axillæ.

The points of interest in the case are (1) the complete absence of the uterus; (2) the influence of this in causing twisting of the ovarian pedicle; (3) the remnants of incompletely canalised and unfused Mullerian ducts, represented probably by the peritoneal fold across pelvis; and (4) the failure of complete sexual characteristics to develop in spite of the presence of an ovary.

---

* Since the above was written I have confirmed my findings made in 1929 that the virus bodies of foot-and-mouth disease are easily seen in the filtrate by this and other methods In a paper shortly to be published a description of these elementary bodies with photographs will appear.

I am indebted to Mr. R. S. Lawson, hon. surgeon to the infirmary. for permission to deal with the case and to publish it.

IODOFORM POISONING FOLLOWING THE USE OF B.I.P.P.

By R. Cunliffe Shaw, F.R.C.S. Eng.
HON. ASSISTANT SURGEON TO PRESTON ROYAL INFIRMARY

An intelligent girl, aged 8. was admitted to the Preston Royal Infirmary with tuberculous adenitis involving the glands in the submaxillary triangle on the right side of the neck. On April 25th, 1932, at 3.30 P.M., I removed the gland and evacuated the contents of a tuberculous abscess, the floor of which was densely adherent to the internal jugular vein. In dissecting it free the vein was punctured and the lateral ligature applied; apart from this the operation was carried out on the usual lines. The wound was swabbed with ether and smeared with B.I.P.P., the surplus being removed on a dry gauze swab; about 1 c.cm. of the paste was used. The wound was closed with a rubber drain.

The following startling train of symptoms ensued.

At 9 P.M. on the evening of operation there was a pulse-rate of 132, and she appeared somewhat restless, but settled down for a short time after nepenthe ♏ 10. At 6 A.M. the following morning she became suddenly delirious, with a barely countable pulse of 178, and a temperature of 100° F. Camphor in oil was given hypodermically, and the pulse-volume improved. Shortly after this there was an evacuation of bulky stools containing large quantities of mucus and blood combined with a blood-stained vomit. At 9.45 A.M. the pulse was barely perceptible, the respirations 32, of the Cheyne-Stokes type, and the temperature 99°. The child was still delirious, she vomited everything given by the mouth, and there was constant tenesmus and passage of blood and mucus; the skin was hot and dry, but free from any sign of rash.

I must confess that after having used B.I.P.P. so often without untoward result it never occurred to me at this stage that I was dealing with iodoform poisoning. The various suggestions made, such as the infection of the vascular system with a massive dose of tuberculous toxins or the presence of thrombosis and emboli, were easily discounted after further consideration.

The condition reached the crisis at 4 P.M. on the day after operation. The hourly pulse-rate from 10 A.M. to 4 P.M. on this day was as follows: 172, 176, 164, 184, 180, 184, 188. Collapse set in, and the temperature fell to 97°, the fall being accompanied by a low muttering delirium. It was only at this juncture that the diagnosis of iodoform poisoning occurred to me. The wound was opened at both ends, and irrigated with a 10 per cent. solution of sodium bicarbonate, and was noticed that an appreciable amount of iodoform appeared in the washing. Following the irrigations, moist dressings of the same solution were applied. Glucose was given per rectum, and small quantities of arrowroot by the mouth, although the latter were generally rejected. Salines were also given subcutaneously and intravenously.

The results of this treatment were striking; the pulse-rate fell to 132, the respirations became regular and slowed down to 18–20, and the temperature rose to 99°. The stools, although still frequent, became only slightly blood-stained. The irrigations were continued three-hourly for the next two days, and was very noticeable that after the majority of the washouts the pulse-rates showed a considerable fall, whilst during the period before the next irrigation there was a steady rise towards the former level.

On the fourth day there was evidence of a subsidence of the intestinal irritation and a general fall in the average pulse-rate, but a new symptom made its appearance. The child lay in a drowsy state responding only to loud-spoken questions, and giving muttered replies. The pupils were contracted, and she lay in a posi [illegible] condition resembling the stage of [illegible] the concussion. The stomach w [illegible] would retain only small quantities of fluids and semi-solids; vomiting did not cease until the sixth day. During this period the wound irrigation was gradually discontinued and the child was fed with small quantities of sweet fluids, and 20 per cent. of glucose was given per rectum. Her movements in bed were restricted by sand-bags and sheets to prevent her sitting up suddenly, for fear of fatal cardiac syncope. The condition of cerebral irritation gradually subsided after two or three days, and was followed by a drowsy lethargic status, during which she slept most of the day, and from which she slowly recovered to normal mentality.

In this particular case I am convinced that apart from an evident idiosyncrasy to iodoform the symptoms were aggravated by the use of a paste which was too thick in consistency, preventing the spreading of an even film of the emulsion over the wound; in addition, the usage of ether for washing out the wound would also assist in the solution of the small particles of iodoform and their absorption by the tissues.

In looking through the published records, one is impressed by the rarity of reported cases, and by the absence of caution in those people who have advocated the use of iodoform preparations for surgical purposes. For example, Moorhof, in 1905, in advising the use of iodoform bone-plugs, stated that in 220 cases he had never seen one of iodism, and in a girl of 14 he had used 200 g. of his iodoform paste. The cases that have been reported (and they are generally to be found in the literature of the close of the last century and the first decade of this) fall into three groups:—

(1) Those which exhibit cutaneous eruptions only.

(2) Those where psychological phenomena were the principal symptoms.

(3) Those which exhibit a dramatic constitutional reaction characterised by: rapid pulse-rate, high temperature and dry skin, vomiting and diarrhœa, great restlessness and delirium, and rapid loss of weight.

It is suggested that this latter acute type of iodoform poisoning is due to stimulation of the thyroid gland, resulting in the production of a temporary thyroid toxæmia. The case I have recorded here undoubtedly belongs to this group. It is noteworthy because it shows, firstly, the vital necessity of a correct diagnosis, and, secondly, the speedy response to treatment by irrigations, salines, and glucose.

North of England Obstetrical and Gynæcological Society.—At a recent meeting of this society, held in Manchester, Dr. F. H. Lacey delivered a presidential address on Cæsarean Section. He began by tracing the history of the operation from Roman times, and by describing early operations, one by Barlow of Bolton in 1793, and one by Trantma of Willenberg in 1600. The reported mortality of 84 per cent. from 1737–1860 was reduced, he said, by Porro in 1877 as a result of supravaginal hysterectomy being also performed. After referring to Sanger's operation in 1882, and Osiurder's lower segment operation in 1865, he quoted more recent figures such as those collected by Routh (6·1 per cent. in 602 cases for 1906–1910) and Spencer (maternal mortality 3·3 per cent., and infantile mortality 10 per cent. in 120 cases). The reasons, he thought, for the present abuse of the operation were: (1) demand on the part of the patient for a shorter and less painful labour; (2) an exaggerated idea of the value of the fœtal life as compared with that of the mother; and (3) extension of indications to include the convenience of husband, patient, or doctor. The lower segment operation was preferable if the patient was in labour or was potentially septic, and when this variety of operation was performed the transverse incision was desirable. Dr. Lacey then gave an analysis of 200 of his recent hospital operations. There were only two deaths in the series—one from broncho-pneumonia and the other in a case complicated by many adhesions which followed two previous Cæsarean sections. One operation, he said, did not preclude a subsequent normal confinement. Cæsarean section for eclampsia, although not popular in this country, was apparently more successful on the continent. Open ether was the anæsthetic used in the majority of cases, but spinal and other special forms of anæsthesia might be strongly indicated in such conditions as toxæmia of pregnancy.

MEDICAL SOCIETIES

TUBERCULOSIS ASSOCIATION

AT a meeting of this association, which was held in London on Jan. 20th, Prof. S. LYLE CUMMINS spoke on

Tuberculosis and the South African Native

He said that to the student of tuberculosis the South African Tuberculosis Report[1] presented most interesting problems. One of these was the relation between the extreme tuberculosis susceptibility observed by Borrel in the Senegalese levies brought to France for the war and thus brought into contact with tuberculous infection for the first time, and the almost equally marked susceptibility of the native miners on the Rand, recruited from the territories where tuberculosis was now known to be endemic. The Borrel type might be correctly described as the tuberculosis of virgin soil, while the South African type would be better called the tuberculosis of hyper-allergic soil. The very extensive and important tuberculin tests carried out in the course of the South African investigation proved that those African mine recruits were not merely tuberculin-sensitive, but were so markedly sensitive as to present a new phenomenon in tuberculo-allergy. Whereas in Wales only 2·3 per cent. of adult males reacted to an intradermal test of 1 in 10 million and only 5·5 to 1 in 1 million dilution of tuberculin, the corresponding figures for the South African mine recruits were 48·6 and 51·5, according to the observations recorded in the report. These figures justified the application to the tuberculosis of these persons of the term "tuberculosis of hyper-allergic soil." Follow-up work had proved quite definitely that these hyper-allergic persons were liable to acute fatal tuberculosis very similar to that observed by Borrel in non-reactors; and, further, that their liability varied directly with the severity of their reactions to tuberculin. Those natives whose reactions were noted as "positive plus" on arrival were found to be more liable to develop tuberculosis during subsequent mining service than the natives who were merely recorded as "positive," and the latter were more liable than those classified as "negative." Prof. Cummins pointed out, however, that the dilution of tuberculin used for these tests was very high—1 in 5000; observations in Wales had shown that no less than 62·5 per cent. of adult males who were negative to 1/5000 tuberculin were positive to 1/1000, 87·5 per cent. to 1/100, and 99 per cent. to 1/10. Thus the "negative" category in the South African tests must have included a large number of those who would have been reckoned positive if more concentrated tuberculin had been used. This South African group might also have included a certain small proportion of genuine "virgin-soil" natives of the Borrel type, so that the number of positives included in the negative group could not be deduced from any analogy with the figures from Wales. There was evidence that the Borrel type of "virgin-soil" susceptibility was not yet entirely lost as a phenomenon of the industrialisation of African natives. The prevalence of the "hyper-allergic" type was, however, of greater practical importance, since this implied that contact with subinfections had failed to produce in these natives any degree of tuberculo-resistance comparable to that of Europeans.

ACQUIRED RESISTANCE

Were they to infer from this that the theory of acquired resistance to tuberculosis resulting from subinfection was untenable, and that some other explanation of the relative immunity of Europeans as compared with Africans must be sought for? Prof. Cummins held that such an inference would be rash. In experimental tuberculosis, the fact that a previous mild infection conferred marked relative immunity to subsequent reinfection was established. Even among "hyper-allergic" *Africans, clinical* observations proved that the long-service natives, exposed to occasional infection over long periods, and at last developing the disease, tended to possess a greater power of controlling their temperature and of keeping their systemic disturbance within bounds than those natives who developed their tuberculosis earlier in their mining service. What, then, of the increased liability to develop tuberculosis which had been shown to go with markedly positive tuberculin reactions in these "hyper-allergic" mine recruits? How did it happen that the increased exposure to infection which must presumably underlie these "positive plus" reactions led, in the case of recruits, to increased liability, while the prolonged opportunities for getting infected which appertained to long mine service led, not to increased liability but to increased toleration and increased resistance? The answer would appear to be that exposure to heavy infection under tribal conditions was one thing, and prolonged exposure to casual infection on the mines quite another. The first led to the establishment of larval but often active lesions which, while producing marked allergy, were very liable to flare up into generalised disease; the second led on to the development of some degree of resistance so that the disease when it developed tended to assume a more benign character. The lesions which underlay the hyper-allergic type in these natives were apparently impossible to detect by routine physical examination, and were probably situated in intrathoracic and intra-abdominal glands, where they escaped diagnosis. It might be assumed that the more severe reactions were associated with a greater liability to disease because they were the result of heavier infections and more active lesions. The less reactive groups owed their diminished risk to the fact that in them the lesions of previous infection were of smaller extent and less activity, calculated to lead to a slighter degree of allergic potential. The "positive plus" reactors possessed what Prof. Cummins had described as an "acquired liability" to the disease.

ALLERGY DISTINCT FROM IMMUNITY

If this concept were accepted, then the important biological deduction followed that, in tuberculosis, allergy could be distinct from immunity. It was clear that these natives, exposed to infection under tribal conditions, responded not so much by the production of tuberculo-immunity as by the development of extreme tuberculo-allergy, and though it was true that this hyper-allergic phase might be an early stage on the road to resistance, it was not the same thing as resistance, nor was it even accompanied by any appreciable amount of resistance to the disease. Its development would appear to render the individual liable to the toxic phenomena of over-severe reactions to auto-tuberculin which resulted in acute and fatal symptoms when localised lesions became generalised under physiological stresses.

---

[1] See THE LANCET, Jan. 14th, p. 100.

Under tribal conditions the African appeared to tolerate tuberculous infection. It was only when he was exposed to new and trying conditions that his larval lesions showed a tendency to sudden generalisation, and to pass into a type of disease so rapidly fatal that the average period of survival in the mine hospitals was only about 33 days.

The African native seemed to differ from the European in his response to tuberculous infection, and his inadequacy might, perhaps, be similar to that manifested by the special strains of guinea-pigs produced through in-breeding by Lewis and Loomis. Tuberculosis had probably become endemic in the native territories of South Africa only recently, and a much longer time and many generations might be necessary for the acquisition of enhanced powers of developing resistance by African natives.

Prof. Cummins concluded by urging that the African native, with his marked liability to tuberculosis as well as to pneumonia and other inspiratory infections, must be housed, fed, and cared for on expensive and generous lines.

At the evening session Dr. P. ELLMAN, tuberculosis officer, East Ham Tuberculosis Dispensary, read a paper on

Pulmonary Asbestosis

He spoke of the clinical, radiological, and pathological features of the condition, and of the risk of phthisis involved. He said that recent advances in their knowledge of the pneumoconioses had enabled research workers to find out certain characteristic features common to certain industries, the greater part of the work having centred round the subject of: (*a*) silicosis, depending on the presence of free silica; and (*b*) the silicatoses, arising from the inhalation of various dusts of fibrous minerals of the silicate group, including asbestos. Pulmonary asbestosis had come to be recognised as a distinct clinical entity, in which, owing to the diffuse nature of the resulting fibrosis, the degree of respiratory embarrassment was usually greater than that of an equally advanced case of silicosis, and which was in fact a more severe disease than the latter.

After a short historical survey of the development of a knowledge of pulmonary asbestosis as a clinical entity, and a review of the chemistry and industrial uses of asbestos, the speaker went on to describe the clinical features of pure pulmonary asbestosis.

CLINICAL FEATURES

The onset of symptoms and their severity depended to a great extent on the nature of the work and of the amount of dust inhaled. Symptoms might be altogether absent, despite the presence of clinical and radiological signs. In Dr. Ellman's experience, dyspnœa was one of the earliest symptoms which at first only occurred on exertion but which became progressive until ultimately dyspnœa and even orthopnœa might occur, and not only after effort. A harsh, non-productive cough and fleeting chest pains would sooner or later accompany the dyspnœa. Expectoration was often absent, and when present was usually scanty in amount and of a tenacious glairy mucoid nature. In the winter months the sputum was usually more abundant and often more purulent. True hæmoptysis had been absent in all his cases, even blood-stained expectoration having been exceptional. Night sweats and giddiness were occasionally found. Anorexia might occur early, but was usually a feature of the more advanced cases, this also being true of cyanosis. Emaciation out of all proportion to the physical signs had mostly been a distinctive feature. Finger clubbing was present in the more advanced cases where bronchiectasis was usually present. A characteristic skin lesion on the hands or legs, known as "asbestos corns," was complained of by many of his patients. While most of the symptoms enumerated were common to silicosis, the more distinctive features of asbestosis were the cyanosis and dusky complexion, anorexia, and emaciation and loss of weight out of all proportion to the physical signs. Examination of the chest showed a very limited chest expansion, especially at the bases where the fibrosis began. The apices were usually retracted. The percussion note was impaired, particularly at the bases. Auscultation showed diminution of breath sounds. The adventitious sounds—fine, dry, crackling râles—were characteristic of the disease. The physical signs, in short, were those of a basal fibrosis, usually spreading upwards. Radiological examination showed in the later stages a fine diffuse punctate mottling (in marked contrast to the coarse nodular mottling seen in silicosis), confirming the clinical evidence that the disease was characterised by a fine diffuse fibrosis beginning at and involving principally the lung bases.

PATHOLOGICAL FEATURES

The macroscopic appearance of the lungs and pleura showed that the visceral pleura was usually markedly thickened, and that the pleural sacs might be partially or even completely obliterated by dense fibrous adhesions. Microscopically the essential features of pulmonary asbestosis were: (1) a chronic interstitial fibrosis of the lung, and (2) the presence of characteristic asbestosis bodies within the alveoli and embedded in the fibrous tissue either separately or in clumps. The interstitial tissue was everywhere increased, so much so that in some cases the alveolar structure could no longer be detected, while in other areas there was evidence of compensatory emphysema. It was in and around the densely fibrosed areas that the bodies were found in the greatest profusion, and tended to occur in radially arranged clumps. Asbestosis giant cells, first described by S. R. Gloyne, might be present in the connective tissue. This giant cell was larger than the tuberculosis giant cell, and the cytoplasm had a stippled and pigmented appearance compared with the structureless caseating appearance of the tuberculosis giant cell. Asbestosis bodies—the highly characteristic golden yellow bodies found in the sputum and fibrosed lungs of asbestos workers—had been found to be present in autopsies of all cases of pulmonary asbestosis. In the sputum these bodies usually occurred singly or in groups of two or three, but when they were more numerous they might be seen in radially arranged clumps—an occurrence indicative of disintegration of lung tissue, either by simple suppurative broncho-pneumonia or by secondary tuberculous infection. The mere presence of these bodies in sputum, while they would indicate exposure to asbestos dust, could not alone justify a diagnosis of pulmonary asbestosis. The diagnosis depended on the cumulative findings: (*a*) opportunities for inhaling asbestos dust; (*b*) clinical evidence of a pulmonary fibrosis; (*c*) radiological evidence of a fine, diffuse pulmonary fibrosis; (*d*) asbestos bodies in sputum, fæces, or lung tissue. It was remarkable for how long asbestosis bodies persisted in the sputum, even when the period of exposure had been very short. In one case exposed to the dust for only ten weeks the bodies were present in the sputum nearly five years later, suggesting that once the bodies were formed they remained more or less permanently in the lung.

With regard to prognosis Dr. Ellman said that an interesting feature of the disease was the extreme length of time that elapsed as a rule between the exposure to the dust and death. The disease was progressive even after cessation of work, and there could be no doubt that without adequate protection the prognosis in pulmonary asbestosis was grave, the gravity varying directly with the degree of concentration of the dust to which the worker was exposed. The first symptoms of the disease were observed, as a general rule, from 4 to 20 years after exposure, the time depending upon the nature and concentration of the dust. He briefly outlined preventive measures before passing on to the question of

TUBERCULOSIS RISK IN ASBESTOSIS

Until quite recently it had been assumed that it was comparatively rare for a pure asbestosis to be complicated by phthisis, and some authorities still maintained that the effect of asbestos and the lung changes induced thereby were due to silica. The constant findings of the asbestosis bodies in the lungs, however, apart from anything else, refuted such an idea. The effect of inhaled dust on the development of a pulmonary infection, especially tuberculosis, was of great clinical importance. Dr. Ellman referred to E. H. Kettle's observations on various dusts, and his classification of them into active or inert substances. Both silica and asbestos came into the group of active dusts, producing active lesions in the subcutaneous tissues as well as a serious pulmonary fibrosis. Kettle had also found that the active dusts had a definite influence on a tuberculous infection, assisting the growth of tubercle bacilli. In Dr. Ellman's own series of 17 cases, the majority of whom were not at work, six had tuberculosis in addition to asbestosis, the disease being active in four of these. That there was a definite risk of tuberculosis in asbestosis appeared to be beyond a doubt, but further work would have to be done before the degree of risk could be assessed. Existing uncomplicated cases would have to be observed, and their development followed by repeated clinical and sputum examinations and serial skiagrams.

LIVERPOOL MEDICAL INSTITUTION

At a pathological meeting of this institution held on Jan. 19th, with Mr. F. Strong Heaney, Vice-President, in the chair, Prof. M. J. Stewart (Leeds) read a paper on

Silicosis and Allied Diseases of the Lungs

He said that the term anthracosis should be reserved for conditions resulting from the inhalation of carbonaceous dust, which produced a fibrosis of the lungs limited both in severity and extent. It did not conduce to tuberculosis. Dense or extensive fibrosis in coal miners was due to an accompanying or antecedent silicosis, and was met with chiefly among anthracite miners. He pointed out the difference in the gross and microscopic anatomy of silicosis and asbestosis; the former was nodular, whorled, mainly central in distribution, and involving especially the middle and upper parts of the lungs; the latter diffuse and mainly basal. The tendency to tuberculosis was significantly less in asbestosis but none the less very important. Asbestosis was definitely a more serious disease, proving fatal on an average after 13 to 15 years' employment as compared with 32 to 42 years in silicosis. Prof. Stewart gave some account of the morphology, distribution, and mode of formation of the asbestosis body, and discussed the significance of its presenec singly or in clumps in the sputum. He described the gross silico-siderotic lesion of the lungs met with in hæmatite miners in the West Cumberland ironstone field, and suggested that the victims of this severe disease were mainly those men who were employed on the dry mechanical drill from the time of its introduction in 1913 until its replacement by the wet drill a few years ago.

DISCUSSION

In the discussion which followed, Prof. J. H. Dible asked Prof. Stewart what was his experience with the polarising microscope in silicosis cases, as it appeared that in many cases of undoubted silicosis, with typical nodules, no doubly refractile bodies could be demonstrated. It seemed difficult to believe that these became dissolved subsequent to the formation of the nodule. Might the resistance of animals to pneumoconioses be due to the greater complexity and length of their upper air-passages? Man was not only less well protected in this respect but was also to some extent a mouth-breather; and these two factors contributed to his liability to respiratory disease. The toxicity of dissolved silica was definite; acute lesions such as fatty degeneration of the heart and necrosis of the liver might be produced by it. Prof. Dible agreed with Prof. Stewart that there was rarely any real difficulty in distinguishing silicotic lesions from fibrous lesions of tuberculosis.

Prof. J. M. Beattie considered that experimental work on silicosis should, if possible, be carried out by the introduction of the dust into the lungs by inhalation. The fibrous overgrowth could be produced over a comparatively short time if the dust concentration was sufficient, and if each animal was compelled to breath the dust continuously for one or two hours daily. He showed photographs in support of his contention that conditions similar to those seen in early cases of silicosis could be reproduced in guinea-pigs by the inhalation method. He still believed that the irritative action of the particles played some part in the process. In his view the prevalence of tuberculosis in cases of silicosis was due to neglect of sanitary precautions rather than to a predisposition to infection with *B. tuberculosis*.

Dr. R. H. Mole asked why asbestosis affected mainly the lower lobe of the lung, and silicosis the upper and middle areas.

Dr. C. Allan Birch asked why tuberculosis was less frequently associated with asbestosis than with silicosis.

Dr. C. O. Stallybrass referred to the frequency with which silicosis turns up in occupations in which the risk would not have been anticipated, such as in cotton carders and men engaged in polishing the heels of boots. He discussed the greatly increased danger of an associated inhalation of silica with a simultaneous infection of tuberculosis.

Dr. R. W. Gemmell said that radiologically the differential diagnosis between silicosis and tuberculosis was often impossible. It was very difficult to say where silicosis ended and tuberculosis began. It was difficult to get a history from masons, who usually denied having hæmoptysis and cough for fear of losing their job.

REPLY

In replying to the points raised in the discussion, Prof. Stewart said that undoubtedly solution of silica particles went on in the lung substance; it was the soluble silica which produced the pathological defects. Optically active particles slowly disappeared from silicotic nodules. Locally, colloidal silica produced an intense coagulated necrosis followed later by endothelial cell reaction and proliferation of fibroblasts round the lesion. In rabbits and guinea-pigs asbestos fibres certainly got into the lungs and produced asbestosis bodies, but the pathological changes were slight. He was unaware of any statistical evidence showing that cancer of the lung or bronchus was particularly common in cases of pulmonary fibrosis due to dust. He had seen at least two cases with that association. It was interesting that in animal experiments it was not possible to produce pulmonary fibrosis with ground-up asbestos. He had seen acute silicosis in (1) sandblasting; (2) the making of abrasive soaps and powders. The lesion here still tended to be focal but did not present the densely collagenous whorled character of chronic silicosis; it was rather an active fibroblastic proliferation perivascular in distribution. He was interested to hear that in Sheffield Prof. Beattie had seen only two cases of silicosis in knife-grinders in whom tuberculosis was *not* present. He agreed that Dr. Bridge's figure, 56·6 per cent., was probably an under-estimate. He thought that the tendency for pulmonary fibrosis in asbestos workers to be mainly basal was due to the character of the dust. It consisted of fine fibres of varying length, and it was probable that the action of gravity played an important part in getting them well into the parenchyma of the lung. They could only reach the lung alveoli by the fibre passing end-on. It was very difficult to have systematic X ray examination of any particular group of workmen, as they were liable either to be scared and think they would lose their job, or get inflated notions as to the possibility of compensation. Tylecote and Dunn, and W. E. Cooke, of Wigan, described bodies somewhat resembling asbestosis bodies in the lungs of coal miners who had never been near an asbestos factory. One reason why tuberculosis was more prevalent in cases of silicosis than in cases of asbestosis was that the latter disease was much more rapidly fatal; another explanation was the insanitary habits of knife-grinders. Silicosis was a disease of males essentially, asbestosis largely a disease of females. The general hygienic conditions in asbestos factories were probably pretty good. He was interested to hear Dr. Stallybrass's opinion that silica rather than silicon was the danger. It was probably a question of solubility. Carborundum (silicon carbide) was found by E. H. Kettle to be almost inert on local inoculation. He was interested to hear of the frequency of pulmonary fibrosis among the masons engaged on the Liverpool Cathedral and the drillers and quarriers in the Mersey Tunnel.

LONDON CANCER SOCIETY

THIS society, which was recently formed, held its inaugural meeting, under the presidency of Mr. J. P. LOCKHART-MUMMERY, on Jan. 27th at 144, Harley-street, W.

Mr. T. YOUNG SIMPSON, hon. sec., and Dr. P. CAVE, hon. treas., explained that the objects of the society were to study, as far as possible, every aspect of the cancer question and to report on new methods of treatment and new pathological and surgical methods of diagnosis with a view to the discovery of some common ground of progress. They appealed strongly to the profession to attend the meetings and to bring forward any new idea, improvement in technique, or practical discovery which might suggest a new avenue of exploration or assist in alleviating or curing any form of malignant disease. There was already a feeling amongst the more sanguine members that before long cancer might be treated without some of the more serious surgical methods now in vogue and possibly by quite simple medical means.

Dr. PAUL CAVE read a paper, illustrated by radiograms, on Osteoplastic Metastases in Cases of Cancer of the Prostate.

In one of his cases a man, aged 50, with no initial symptoms of prostatic trouble, suddenly developed backache. X rays showed extensive osteoplastic deposits in the lower dorsal, lumbar, and sacral vertebræ. It was then discovered, on routine examination, that the prostate was hard and knobby. Complications developed rapidly, including incontinence of urine and fæces, paralysis and anæsthesia of both legs—all symptoms of pressure upon the spinal cord. The cervical and upper dorsal vertebræ and the skull were not affected.

Autopsy revealed a stony-hard condition of the affected vertebræ, the chemical composition of the bone showing a 44 per cent. increase in the calcium carbonate content. The marrow spaces were shown on decalcification to be filled with solid masses of epithelium. Practically no marrow remained and the extension of the growth into the spinal canal had severely compressed the cord. The growth (an adenocarcinoma) in the prostate extended into the bladder and pelvic tissues. There was no rheumatic history and the Wassermann reaction was negative. The lungs, liver, kidneys, and spleen were normal. There was no affection of skull, brain, or meninges.

Dr. Cave said that it was difficult to explain why sclerosis should develop in bone instead of osteoporosis, and why only the lower spinal vertebræ should be affected. If the sclerosis of bone was an effort of nature to strangle the growth why did it occur specially in cases of prostatic cancer and not in all cases of bone metastases. A possible explanation was: (1) spread from the primary growth through the lymphatics, whereas osteoblastic metastases follow vascular dissemination; (2) cancer cells invade the bone through the Haversian canals and lymphatic channels after the ligaments and periosteum have been infiltrated; (3) the various blood-vessels become choked with cancer cells and so the blood-supply of the parts is diminished; (4) this restricted blood-supply deprives the bone cells of parathyroid secretion, causing retention of calcium in the form of calcium carbonate; (5) the new bone encroaches on the Haversian canals and medullary spaces and makes the bone abnormally dense and hard.

Dr. MAURICE SHAW read a paper on Some Medical Aspects of Cancer. He held that it was an advantage for those who suffered from apparently innocent complaints to submit themselves to a thorough and complete medical examination from time to time in order to free themselves from the subconscious bogy of cancer. He said that often patients improved in health when a fear to which they would not give expression in words was dispersed by a definite statement excluding any form of malignant disease. He expressed his confidence that by team-work it was now possible to verify or exclude the majority of cancerous tumours, but conceded that up to the present no serum test for the presence of cancer in the system had proved efficient. In his view intrathoracic cancer, growths in the large bowel, malignant prostate, and so on, were sometimes missed, because trouble was not taken to investigate matters more thoroughly; he urged practitioners to keep abreast of the times. He believed that a society such as the London Cancer Society could do much good by hearing the views of experienced clinicians, surgeons, pathologists, and laboratory workers, from a careful sifting of which definite advances might be made.

Dr. DAVID DE SOUZA, Mr. MCNEILL LOVE, Dr. C. E. M. LOWE, Dr. S. W. H. STUART, and others took part in the ensuing discussion.

REVIEWS AND NOTICES OF BOOKS

Gray's Anatomy

Twenty-fifth edition. Edited by T. B. JOHNSTON, M.B., Ch.B., Professor of Anatomy in the Medical School of Guy's Hospital. London: Longmans, Green and Co. 1932. Pp. 1478. 42s.

IT is no surprise to learn that the last edition of this famous work was so favourably received that the present issue was called for earlier than had been anticipated. We have little doubt that the history will repeat itself. It is a real pleasure to read the descriptive accounts of bodily structure in this book. The editor has rewritten a good deal of the section on surface anatomy, and has incorporated in the embryology section many of Prof. J. E. Frazer's recently published views; otherwise the main changes have been in small revisions and in the addition and replacement of figures. It is to be hoped that Prof. Johnston's ardent wish may be fulfilled, and that the questions of terminology which have been upsetting the anatomical world for so many years will soon be settled to the satisfaction of English anatomists. The amelioration of the student's lot, in this respect, produced by the simple use of English equivalents whenever possible, is a move in the right direction which is here adopted. A fine book, commendable in every way.

The Colon, Rectum, and Anus

By FRED W. RANKIN, M.D., F.A.C.S., Associate Professor of Surgery, the Mayo Foundation; J. ARNOLD BARGEN, B.S., M.D., M.S., F.A.C.P., Assistant Professor of Medicine; and LOUIS A. BUIE, M.D., F.A.C.S., Associate Professor of Proctology at the Foundation. London: W. B. Saunders Co., Ltd. 1932. Pp. 846. 50s.

THIS authoritative work contains a historical account of the diagnosis and surgical treatment of disease of the large bowel and rectum, and incorporates a record of the clinical experience and statistical data accumulated at the Mayo Clinic. Certain sections of the book demand especial notice. The chapter on megacolon gives a complete summary of the modern view of the pathology of this condition, and an indication of the hopeful results which are being obtained by sympathectomy. The long chapter on chronic ulcerative colitis provides a masterly exposition of the subject. Bargen's diplococcus is stated to have been isolated in pure culture from approximately 80 per cent. of patients with chronic ulcerative colitis examined at the Mayo Clinic during recent years, and a similar organism has been obtained by blood culture from certain fulminating cases of the disease. It is not believed at this clinic that the dysentery bacillus plays any part in the immediate ætiology. The incidence of complications, such as stricture, malignant disease, and peritonitis, is discussed, and the treatment is described in a helpful way. A large portion of the book is naturally devoted to the subject of carcinoma of the colon and rectum. Surgical excision is considered to be the method of choice in dealing with malignant disease of the rectum; the patient's condition, together with the site and characteristics of the growth, being considered in determining the most suitable surgical procedure. A cautious attitude is adopted as to the value of radium in rectal cancer. The final chapter on operative procedures contains many features of interest, including the methods of resection of the colon with aseptic anastomosis, and Rankin's method of "obstructive resection." A two-stage abdomino-perineal excision is described, the excision operation being started from the perineum at the second stage. For the treatment of megacolon the method of exposure and division of the presacral and inferior mesenteric nerves is described.

The bibliographies given at the end of each chapter show what an immense amount of original research has been done in this branch of surgery at the Mayo Clinic. The volume forms an impressive and valuable monument to the work of the authors and their colleagues, as well as a critical and up-to-date book of reference on the colon and rectum. It should be widely studied.

The Principles and Practice of Psychiatry

By ALEXANDER CANNON, M.D., and EDWARD DUNCAN HAYES, M.D. London: William Heinemann, Ltd. 1932. Pp. 437. 25s.

THIS work is an attempt to write a compendium of modern psychiatry for the use of students. While the divisions and proportion of the work are on the whole adequate, the same cannot be said of the subject matter which is presented in an undigested and fragmentary form. At places, owing to the lecture-note style, the statements are incoherent, or, by omission of relevant data, misleading. After an introductory chapter on general principles the forensic and criminal aspects of psychiatry are considered, followed by sections on mental deficiency and abnormalities of behaviour in children. Psychology is the subject of the next three chapters; then systematic psychiatry is dealt with, especial attention being given to the endocrine glands in this connexion. The application of physiology to psychology and of biochemistry to psychiatry are discussed at some length, and a chapter on methods of examination concludes the book, except for an appendix which is a medley of tables of doses, psycho-analytical symbols, anatomical diagrams, classification lists, and legal forms and other odds and ends, including the deaf and dumb alphabet. The production, for a text-book, is too uncritical and subjective; this is particularly evident in the section on psychotherapy. The book seems to be compounded of facts collected without due sifting from many sources, and of personal views which require more support before inclusion in a text-book for students.

The Failing Heart of Middle Life

By ALBERT S. HYMAN, A.B., M.D., F.A.C.P., Cardiologist, Beth David and Manhattan General Hospitals; and AARON E. PARSONNET, M.D., C.M., F.A.C.P., Attending Physician and Cardiologist, Newark Beth Israel Hospital. Philadelphia: F. A. Davis Company. 1932. Pp. 538. $5.00.

UNDER an attractive title Dr. Hyman and Dr. Parsonnet deal in great detail with the various types of heart disease which result from lesions of the coronary arteries. The first six chapters are devoted to an anatomical, physiological, and pathological introduction to the subject, and the next five to the syndrome of "myocardosis," this term being applied, instead of the more familiar title of myocardial degeneration, in lesions other than the inflammatory ones resulting from myocarditis. Three sections of the book are devoted to coronary occlusion, to the electrocardiographic changes in coronary disease, and to angina pectoris; while in a final section the authors deal with medico-legal problems arising in cases of sudden death.

The importance of the great degenerative group of cardiac lesions needs no emphasis, for the advances in our knowledge of the clinical manifestations of coronary occlusion in the last 20 years only serve to emphasise the extent of our ignorance concerning other types of angina. As a book of reference this will be welcomed by all who are trying to explore this field; but at the same time one cannot but regret that the authors have in places lost sight of their objective. While the chapters dealing with pathology are to the point and are well illustrated by microphotographs, those on the clinical aspect are at times unnecessarily veribose and treat in great detail topics which should already be familiar to all readers whose clinical training is not entirely negligible. Similarly in the section on electrocardiography six chapters are devoted to disturbances of the heart's rhythm. While it is recognised that almost every type of abnormal electrocardiogram may be met with in the degenerative group of cardiac diseases, this is surely not the place to discuss the symptomatology and diagnostic features of the various types of arrhythmia. The reader who is prepared to plod through a book of over 500 pages on coronary arterial disease deserves to be given credit for at least an elementary knowledge of electrocardiography. In a future edition much padding might with advantage be omitted. A minor point is that the lettering of the electrocardiograms is not that commonly adopted, the initial major ventricular deflexion being marked R irrespective of whether it happens to be positive or negative. The medico-legal section is a useful innovation, but would be easier to digest if more space were devoted to a discussion of the legal principles involved even if fewer actual cases were quoted to illustrate these principles. The bibliography includes 1250 references but even so appears to be incomplete, several original papers which are referred to in the text being omitted.

Journal of Pathology and Bacteriology

THE January issue (Vol. XXXVI., No. 1) contains the following papers. Familial and Bilateral Tumours of the Carotid Body, by W. H. Chase (Montreal). Two sisters with tumours of the carotid body, in one of them on both sides. They were removed and one of the women died. The tumours had the typical structure of the carotid body; there were no metastases and no general symptoms were identified.—On the Significance of Nerve-fibres in Human Malignant Neoplasms, by G. M. Ryrie (Glasgow). The nerve-fibres found in carcinomata are not proper to the tumour, but axis cylinders sprouting from the normal nerves injured by the tumour as they do from after any nerve section.—Experimental Liver Disease Produced by X Ray Irradiation of the Exposed Organ, by A. Bolliger and K. Inglis (comment on p. 258).—The Pathological Action of Light: "Light Stroke" and its Relation to "Heat Stroke," by A. G. Levy (London). Mice, sensitised with hæmatoporphyrin and exposed to visible light, die with symptoms very similar to those of heat stroke. Intense irradiation with ultra-violet light does not kill depilated mice if they are kept cool.—Neoplasms in Fish: a Report of Six Cases with a Summary of the Literature, by A. Haddow and I. Blake (Edinburgh). Lymphosarcoma, hepatoma, ganglioneuroma, melanoma, &c.—The Filtration of Herpes Virus through Graded Collodion Membranes, by W. J. Elford, J. R. Perdrau, and W. Smith (London). The diameter of the virus particles is about 0·1 to 0·15 μ.—The Production of Immunity to Vaccinia Virus by Mixtures of Immune Serum and Virus, and the Importance of Phagocytosis in Antivaccinial Immunity, by R. W. Fairbrother (Manchester). Intracerebral inoculation of virus serum mixtures leads to a high degree of immunity; immune blood has more action on the virus than immune serum.—Observations on Salmonella Agglutination and Related Phenomena, by P. Bruce White (London). For experts by an expert.—Species Immunity to Pneumococcus, by H. B. Day (London). In mature pneumococci an antigen is formed which on injection into animals induces immunity to all types of pneumococci; the serum confers a similar passive immunity. The type-specific antigens are formed by young pneumococci, and the more generalised species antigen appears to be derived from them by dissociation of the type-specific substance.—The Production of Staphylococcal Hæmolysin with Observations on its Mode of Action, by J. W. Bigger (Dublin). The production of hæmolysin is inconstant and the best conditions vary with different strains; glycerin and phosphate are useful.—Reticulo-endotheliomatosis, Ovarian Endothelioma and Monocytic (Histiocytic) Leukæmia, by R. Gittins and J. C. Hawksley (Birmingham). In an infant of one year, with a good discussion of the literature.—Sarcosporidiasis in Human Cardiac Muscle, by J. A. Hewitt (London). Accidentally found in histological material.—Production of Tumours in the Fowl by Carcinogenic Agents: (1) Tar, (2) Dibenzanthracene, by P. R. Peacock (Glasgow). Both agents produce tumours on subcutaneous injection, varying from fibromata to highly malignant sarcomata.—Pulmonary Tuberculosis with the Bovine Type of Bacillus in the Sputum: Fourteen New English Cases, by W. M. Cumming, W. M. Foster, R. O. Girdwood, and A. S. Griffith (Grassington, Bradford, and Cambridge). Ten showed evidence of previous glandular involvement. Two autopsies showed no clear difference from cases due to the human bacillus. From one case bacilli of both types were isolated.—Incidence and Correlation with Clinical Severity of "Gravis," "Mitis," and Intermediate Types of Diphtheria Bacillus in a Series of 500 Cases at Leeds, by J. S. Anderson, K. E. Cooper, F. C. Happold, and J. W. McLeod (Leeds). The differentiation previously announced is held to be confirmed: in 425 gravis cases there were 78 examples of paralysis and 50 deaths; in 113 mitis cases, 2 cases of paralysis and no deaths. The distinction between the two in animal experimentation is not so clear.—A Case of Circumscribed Lymphangeiomatous Dilatation of the Lingual Papillæ, by S. McDonald, Junr. (Newcastle). In a boy of 5.—A Method of Staining the Elementary (Paschen) Bodies of Vaccinia, by J. Craigie (Toronto). Mercurochrome, methylene-blue, and methylene azure.—The Influence of Purified Testicular Extract upon the Rate of Absorption of Antitoxin, by D. McClear and W. T. J. Morgan (Elstree). The extract accelerates the passage of antitoxin into the blood after subcutaneous but not after intramuscular injection.—Conditions Predisposing to Urinary Infection after Post-operative Retention, by C. E. Dukes (London). The longer there is any stagnant urine in the bladder, the more likely it is that the few organisms which are always present will be able to gain an infecting foothold.—Phases in the Growth of the "Virus" of Pleuropneumonia on Artificial Media, by J. C. G. Ledingham (London). Minute spores give rise to a delicate mycelium on which fruiting bodies develop from which a variety of bizarre forms arise; subsequently involution sets in and the spores alone remain to start a fresh cycle.

MEMORIAL TO THE MAYORESS OF TORQUAY.—It is proposed to provide an X ray apparatus and an operating table at Whitecliffe Tuberculosis Hospital as a memorial to Mrs. Thomas, the mayoress of Torquay, who was recently killed in a motoring accident.

THE LANCET

LONDON: SATURDAY, FEBRUARY 4, 1933

THE EPIDEMIOLOGY OF WHOOPING-COUGH

IN a paper[1] already reviewed in these columns, Dr. PERCY STOCKS brought out the fact—still too little appreciated—that whooping-cough is now one of the major causes of death in early childhood. In the sequel concluded on p. 265 he shows that in London it must indeed be regarded as the most expensive epidemic disease among children—that is, when the cost is measured in terms of loss of life, acuteness of physical suffering, permanent damage to respiratory, cardiac, or nervous mechanism, and loss of school attendance. Probably the tendency to under-rate its importance, that is yet apparent in the lay and medical mind, is a relic of the latter half of the nineteenth century when its contribution to mortality was overshadowed by those of scarlet fever and diphtheria, both of which caused many more deaths then than they do now. It is partly this attitude to the disease, partly its relative neglect by research workers, that have, no doubt, led to our somewhat scanty knowledge of it and of its control. For instance, in the present state of knowledge Dr. STOCKS believes that the practice of excluding from already infected schools home contacts to whooping-cough cases may actually be harmful. The risk lies in these excluded children spending their time playing with children of pre-school age, for it is on these latter that the mortality falls heaviest. Of the 44,000 deaths in England and Wales attributed to whooping-cough during 1921–30, 97 per cent. were of children under five years of age, while according to Dr. STOCKS's figures for the borough of Battersea the fatality-rate fell from 4 per 100 cases at age 0–1 to 0·2 per 100 at ages 5–10. If exclusion from school is to be of benefit it must be accompanied by effective isolation from younger children, a difficult thing to achieve in poor and overcrowded areas. The contention that "it is best to get it over while they are young" has no justification; for besides the rapid diminution in fatality-rate there is a reasonable chance, of the order of two in five, Dr. STOCKS calculates, that if a child escapes immediate attack he or she may escape the disease altogether.

One of the peculiarities of the epidemiology of whooping-cough that has long been observed is its heavier incidence of mortality upon the female sex. It is the only important cause of death below the age of five years that reveals this peculiarity. Respiratory causes of death, such as tuberculosis, pneumonia, and bronchitis, all show a lower death-rate among girls—15 to 20 per cent. lower than among boys. In measles, scarlet fever, and diphtheria, girls show a slight advantage, about 5 per cent.; yet from whooping-cough they show an extremely consistent disadvantage, their death-rate at ages under five being 20 to 25 per cent. in excess of boys'. From time to time various explanations of this paradox have been advanced—e.g., sexual differences in the formation and development of the larynx, differences in sensitiveness of the nervous system—but no one of them seems adequate to fit the observed facts at different ages. Owing to lack of efficient notification it is not even clear whether this higher mortality-rate denotes a higher incidence of attack amongst females or a higher fatality-rate amongst the attacked (or a conjunction of both). According to the figures which Dr. STOCKS gives for London boroughs there is a significantly greater susceptibility of female infants to attack from birth, and this increases from the fourth year onwards to a 50 per cent. excess by the tenth year. He has no figures to show whether they succumb more easily to attack, but finds in Greenwich that this female susceptibility bears some relation to season. At ages under seven there was in this borough no excess of girls amongst cases commencing from October to January, but an excess of about 20 per cent. amongst cases arising during the other months.

Another curious point brought out by these figures is that the proportions of children known to their parents to have had whooping-cough before entry to school at ages 3, 4, 5, and 6 are greater in those boroughs of London where the population is less dense and better housed. Though, obviously, this may be partly accounted for by more accurate observation and diagnosis in such areas, Dr. STOCKS believes this factor is insufficient explanation, and that increased crowding of the population in the different districts of London not only does not result in increased incidence of whooping-cough but rather the reverse. He believes that the phenomenon can only be explained in terms of latent immunisation. A possibly related phenomenon has been repeatedly drawn attention to by the Registrar-General of England and Wales in his recent annual reports. In this country the mortality from whooping-cough is invariably lower in the rural districts, and yet with decreasing urbanisation a higher proportion of the deaths fall in the first year of life. For instance, in 1930, of the whooping-cough deaths at all ages in rural districts 53 per cent. were of infants under one year old; in the county boroughs the percentage was only 46. In many years still larger differences are to be found, and the characteristic can be observed at least three-quarters of a century ago, when the death-rate from whooping-cough was three times as high. Measles, on the other hand, shows rather what would be expected—the more the overcrowding the earlier the chance of attack and death. Without more knowledge of the case-incidence of the disease in various areas—to which the present study materially contributes—it seems impossible to explain this further curiosity of a disease still epidemiologically obscure.

THE REPAIR OF LIVER INJURY

No organ in the body is more competent than the liver to restore itself to normal by reparative and compensatory growth after certain types of injury. Complete removal of one lobe is followed quickly by compensatory hypertrophy of the remaining parts, and in this way a loss of as much as two-thirds can be made good. Similarly the atrophy produced by tying a part of the portal vein is balanced quantitatively by overgrowth of the healthy parts. When, too, the central part of each lobule throughout the whole liver is destroyed, as in chloroform poisoning, regeneration soon reproduces a normal liver, and this takes place even in starving or ill-fed animals in which the necessary materials for reconstruction are drawn from other tissues rather than from the food.

In all these instances, restoration appears to be perfect, permanent, and functionally quite adequate. But there are other types of injury which seem to be more than the liver can deal with at present, though we may suppose that under the sifting influence of evolution it may some time acquire the faculty of coping with these also. A good example is given by Dr. A. BOLLIGER and Dr. K. INGLIS [1] of Sydney, who have studied the action of X rays on the liver. A single massive dose applied to the exposed organ causes a varying amount of acute necrosis of the liver cells, mostly towards the surface but to some extent also in the depths. This may have a lobular distribution, in which case as usual the central cells are most vulnerable, or it may be massive—i.e., without any reference to lobules. If it is extensive enough, the animals die. If they survive the immediate damage, the dogs seem quite well, and biopsies may show little anatomical change. But sooner or later—5 to 16 months in the experiments described—the animals begin to wilt, lose weight, develop jaundice and ascites, and die with the rather vague symptoms of cholæmia. After death the liver is small and irregularly cirrhotic, with perhaps some areas of indefinite hypertrophy: microscopically there is much overgrowth of connective tissue and disappearance of liver cells, and, in addition, areas of recent necrosis are also generally found. The injury inflicted by X rays is evidently one from which satisfactory recovery is difficult or impossible. The anatomy, histology, and clinical history are reminiscent of the condition in man often called "subacute atrophy," many cases of which have been due to poisoning with trinitrotoluene or organic arsenicals. In this the liver cells have certainly not lost their capacity for responsive growth, for nodular masses of hypertrophy are part of the characteristic picture. But hypertrophy or regeneration which will be functionally adequate seems to be, often at least, impossible, and after a long illness the patient dies of liver insufficiency.

Much the same difficulty arises in trying to explain exactly what happens in ordinary cirrhosis. Often enough the individual lobules are considerably hypertrophied, and larger masses of fresh-grown liver cells are frequently present, yet the disease goes on to an inevitably fatal end. What is the essential difference between chloroform necrosis, which cures itself, and these other forms, which do not? It seems as if it must depend not so much on the destruction of the liver cells themselves, but on the involvement of the framework in which they live, and especially perhaps of the finer details of the complicated blood-supply. In the portal canals the hepatic artery breaks up into capillaries which reunite into venules which join the portal venules to enter the sinusoids at the periphery of the lobules. What this arrangement means functionally we do not yet know. Pathologists, too, have many reasons for thinking that the several concentric zones into which the cells of a lobule may be divided probably have different functions, the due discharge of which may well depend on each of them receiving the right sort of blood. This presumptive guess that the important error in X ray necrosis, in T.N.T. poisoning, and in cirrhosis, is a disorganisation of the blood-supply is borne out by the work of A. H. MCINDOE,[2] who showed, by some beautiful injections, how the normal arrangement is completely upset in ordinary cirrhosis with the result that the liver cells receive relatively little of the portal supply. Incidentally, the facts make it difficult to believe that cirrhosis begins with any necrosis which is strictly lobular in distribution.

◆

BIRTH CONTROL METHODS AND RESULTS

IN this country the birth control movement has now passed out of the crusading phase into the phase in which it has become self-critical and analytical. One of the first signs of this new attitude was the appearance in 1930 of Mrs. SECOR FLORENCE'S "Birth Control on Trial,"[3] in which were summarised the results of a follow-up investigation conducted by her upon the first 300 women who attended the birth control centre in Cambridge. A similar critical attitude characterises the successive publications of the International Medical Group for the Investigation of Contraception which have been reviewed from time to time in these columns. ENID CHARLES [4] has now provided a valuable addition to this class of literature.

It is by no means easy to form an impartial estimate of the results of the practice of contraception. Hitherto practically all the published findings have been based upon the records of birth control clinics—that is to say, of special centres, for the most part organised and financed as private enterprises, by groups of interested persons throughout the country. These findings are open to the criticism that they are based upon the experiences of a selected group of women. A woman may attend a birth control clinic for several reasons, among them because a method previously employed has failed. The clientèle of the clinics cannot be taken as representing unselected examples of married women in the community. In order to meet this criticism, the statistics subcommittee of the Birth Control Investigation Committee drew up, four years ago, a questionnaire which was sent out to women who, so far as possible, were unselected and therefore represented a random sample of the population. It was filled in by the women themselves who were asked not to reveal their names. The material thus furnished provided evidence of a different nature from that yielded by the records of the birth control centres which are compiled by the lay workers and doctors attached to the centres. The questionnaire sought to obtain unbiased answers on the extent to which birth control methods are used in the community, and on the reliability, practicability, effects on health and effects on fertility of different methods. Unfortunately it proved difficult to secure the coöperation of women of the working classes, and the questionnaires were for the most part filled in by women falling in Group I. of the Registrar-General's report of the 1911 census. The greater part of Enid Charles's book is devoted to an analysis of these questionnaires. It also contains analyses of 198 questionnaires sent out by a nurse to women upon whom, in the years since the war, she had fitted Dutch pessaries, and of 400 follow-up reports carried out by the Birmingham Women's Welfare Centre. The volume therefore contains an abundance of statistical material, and, by reason of the fact that the generalisations it contains are based upon first-hand information, stands out from a mass of propagandist literature founded on little else than moral preconceptions and biased impressions. Though it cannot be claimed that any of the three sources of material represents a random sample of the population, they furnish, when taken together, a valuable body of evidence from which it will only be possible to summarise here the salient facts of medical interest.

[4] The Practice of Birth Control. By Enid Charles, M.A., Ph.D. London: Williams and Norgate, Ltd. 1932. Pp. 190. 10s. 6d.

Of 432 women, then, who vouchsafed their experiences, only 12 had employed no contraceptive methods whatever. It will thus be clear that in the group investigated, in which the active reproductive life averaged 12 years, birth control methods of one sort or another are very extensively used. Enid Charles concludes that the sheath and the rubber cap are the most reliable methods, provided that they are used in conjunction with a spermicide or a douche. In these circumstances, assuming that coitus takes place about once a week, the odds against a single conception occurring over a period of about five years are about 17 to 1; and the odds against conception following a single intercourse are about 5000 to 1. Of the two methods above referred to, the combination of a sheath and another method gives the highest degree of reliability, the Investigation Committee's questionnaires here showing a percentage of success of 98 comparing with one of about 75 for the rubber cap combination. A soluble quinine pessary, when used alone, was found to be relatively unreliable, the percentage of success being only 54. The rubber cap combination seems to be somewhat more acceptable on æsthetic grounds than the sheath, which is disliked by a number of the husbands. A question upon the effects of the use of birth control on health and conjugal well-being was answered by 339 women. Of these, 2 found contraceptive methods so objectionable that they were given up, 37 found them unsatisfactory but inevitable, 193 found them in general terms satisfactory, and 107 spoke of them as essential to health and marital happiness: but there was evidence that coitus interruptus was found harmful by many couples who, at one time or another, had recourse to this method. The Investigation Committee's questionnaires also provided evidence on the effects of contraception on fertility. In a series of 420 women desiring pregnancy there were only 17 who were unable to conceive. Allowing for the fact that the sample may be selected as regards absence of sterility, this figure compares favourably with the amount of involuntary sterility which has been computed to exist in the general community, wherein one-sixth of all marriages are thought to be sterile. But Enid Charles adduces evidence that despite its unreliability as a contraceptive, quinine may have an effect on fertility in that, for users of pessaries containing this substance, the period intervening between the discontinuation of use and the moment of conception seems to be unduly prolonged. These are but a few of the findings set forth in this book which should be read by all persons seriously interested in the sociological and clinical aspects of contraception. She has analysed and summarised the complicated material placed in her hands with deftness and lucidity; and the caution with which she advances her conclusions should be an example to all writers upon the subject.

Several of these conclusions are borne out by the annual report for 1931–32 of the Society for the Provision of Birth Control Clinics.[5] Of 97 women who discontinued practising birth control because they wanted a child, 96 became pregnant; and 158 women who, on one occasion, neglected to use the method advised, had unwanted pregnancies. The report further confirms Enid Charles's findings about the frequency with which coitus interruptus is practised by working-class couples, and also about its unreliability. The medical officers of the Walworth women's welfare centre also draw attention to the frequency with which prolonged lactation fails as a contraceptive measure. The method most frequently advised at this centre is a combination of Dutch pessary, a spermicidal ointment, and a douche of soapy water. A case is mentioned of a woman who used the same pessary and syringe for five years. An increasing number of couples are successfully using the sheath. A list of the 17 subsidiary clinics affiliated to the society is available to practitioners. At these clinics up to August 31st, 1932, advice has been given to 47,500 women. Printed leaflets showing the places where centres affiliated to the society have been established, and the times at which sessions are held at these centres, are available on demand.

ANNOTATIONS

EARLY DIAGNOSIS OF MALIGNANT DISEASE

LESS than a year ago[1] we chronicled the formation of the Harley Medical Society, which originated in a desire to foster the scientific spirit among members of the medical group attached to the London Clinic and Nursing Home. Mr. Lockhart-Mummery gave the opening address entitled the Origin of Tumours. We have now received (see p. 254) a report of the inauguration of yet another more specialised society, the London Cancer Society, which first met last week, under the presidency of Mr. Lockhart-Mummery, at 144, Harley-street. It seems doubtful whether the multiplication of more societies in an area already well served by the different sections of the Royal Society of Medicine and by the Medical Society of London will really lead to the advances in knowledge anticipated by some of its members. The proposition put forward at the meeting was that, as regards diagnosis at any rate, knowledge had reached the stage where, if the public would only consent to submit to periodical examination, and all available accessory methods of diagnosis were enlisted, very few malignant growths would remain undetected at an early stage. If we cannot share this optimism it is perhaps a matter of definition. Evidently "an early stage" is considered to be a stage at which the growth though visible or palpable is still operable and no metastases have developed. But every practitioner could reveal tragic stories of cases where vigilance has failed to detect the beginning of malignancy. In fact, except by accident, for example during the routine microscopical investigation of a uterus or a breast removed for another reason, it is probable that really early lesions are never detected. By the time they are palpable or visible by X rays or to the naked eye, they may well, in certain regions, be inoperable. And in the intervals between any routine periodical examinations—which, to be in any degree reliable, must include examination per vaginam and per rectum—a quickly growing tumour may defeat the whole elaborate scheme. Whether the number of growths detected in this way is likely to be worth the risk of developing in healthy persons morbid fears of disease, or of increasing such fears in those who already suffer from them, is a matter of opinion. Mr. Lionel Colledge, in the current issue of the *Practitioner*, which is devoted to articles on the early diagnosis of malignant diseases, says wisely that "it is the doctor, and not the patient who should be the cancerphobe." It is the doctor, too, who will get some surprises from a study of these 14 articles on diagnostic possibilities in cancer of the tongue, the stomach, the throat, the mediastinum, lung, and pleura, the colon, the rectum, the breast, the uterus, bone, the bladder, the prostate, and the testicle. For example, while Mr. Geoffrey Keynes admits that early cancer of the breast is not easy to diagnose, Dr. Izod Bennett boldly declares in connexion with the early diagnosis of carcinoma of the stomach, that "in any particular individual the question of whether or not cancer of the stomach is present can be answered accurately in 99 out of every 100 cases." Obviously the definition of "early" as used by different observers can bear no firm relation to ultimate results of treatment, since the prognosis in breast cancer is immeasurably better than in cancer of the stomach. The omission from the series of the brain and the kidney regions, where diagnosis is especially difficult, is regrettable. The articles are all provocative. Sir Holburt Waring contributes a general introduction in which he outlines the methods of examination available and utters some useful warnings. The conclusion is inevitable from the careful study of these articles that in spite of the many instruments and direct and indirect methods of examination now available, the early diagnosis of malignant diseases is still often very difficult.

YELLOW FEVER IN FRENCH WEST AFRICA

IN the English territories of Nigeria yellow fever is endemic in the coastal regions. This endemicity decreases as one proceeds into the interior, and in the southern zone the disease can only be recognised in its epidemic form. This knowledge is the outcome of studies carried out at Lagos, under the auspices of the Rockefeller Foundation of New York, by the West African Yellow Fever Commission, whose director, Dr. Beeuwkes, has since been pursuing his investigations further north in the French territory by permission of the Governor-General. His object was to try to discover any manifestations there of yellow fever, and to ascertain the most northerly limit of this terrible disease. Dr. Beeuwkes has had the collaboration of Dr. C. Durieux, who joined the members of the Commission in Lagos in April last, and now describes the work undertaken and in progress.[1] The members of the Commission detailed to undertake the expedition included Dr. Mahaffy as leader, Mr. Michailoff as secretary, and various native personnel. They left Lagos on April 11th by rail for Kano, whence further journeys were undertaken by motor-car. On April 14th they reached Zinder, and passed through various townships of the French Niger Colony, the French Sudan, and Dahomey. During the journey 803 specimens of blood were taken in different localities. Wherever possible the data were derived from natives born and bred in the neighbourhood. The determination of the exact district to which different natives of Nigeria belong is extremely difficult on account of the shifting nature of the population; specimens were obtained from women by preference, as they seemed less mobile than the men. The specimens obtained were tested according to the method of sero-protection used by the American Yellow Fever Commission at Lagos. Sawyer's method of sero-protection is the one favoured; a starchy emulsion is first injected into the brain of a white mouse, and two hours afterwards a mixture of serum-virus is injected into the peritoneal cavity. Each serum is injected into six mice, and the different operations are carried out as speedily as possible; 25–30 sera are tried out every three days, and about 300 sera a month are thus tested. The white mouse apparently is the ideal animal for testing susceptibility to the yellow fever virus; up to the present no less than 2000 sera from all parts of Nigeria have been tested. The results of the tests carried out with the specimens of blood collected on the tour of the French territories did not favour the general opinion that the French Niger Province has been free from yellow fever up to recent times. These tests indicated that the disease has existed for several years in the population of this colony. In the Zinder region, the last manifestations of yellow fever appear to have been between the years 1915 and 1919 (the youngest of the positive cases were about 17 years old). At present the disease is localised in the southern zone of the colony on the road from Gouré to Niamey, and it has not yet spread northwards. Dr. Durieux expresses the hope that these investigations will be pursued in order to define the areas where yellow fever is endemic, so that prophylactic measures can be undertaken, and the areas as yet free from the disease protected from invasion.

SEX HORMONES AND UTERINE INFECTION

It is well known that the reticulo-endothelial system plays an important part in resistance against infection, and a fair amount of evidence has accumulated to show that any factor which stimulates the local reaction of reticulo-endothelial cells is of importance in combating a local infection. The reaction of the reticulo-endothelial system in cases of puerperal sepsis was investigated some years ago by Louros, who pointed out that the utility of such methods of treatment as the injection of foreign proteins, of colloidal substances, and of milk probably depends on their stimulating the reticulo-endothelial system. C. F. Fluhmann [1] has lately described experiments on the rabbit uterus which were designed to show the local response of reticulo-endothelial cells to the injection of ovarian and pituitary hormones. The usual technique of injecting trypan-blue was employed, and the test animals were spayed rabbits and rabbits under the influence of œstrin and of pituitary hormones. The local response in the uterus was either one of œstral or progestational hypertrophy. The results obtained showed that either under the influence of œstrin or when in a state of progestational proliferation the uterus contained a large number of macrophages, and it was found that if local injury to the uterus was previously induced by inserting a silk ligature into one of the uterine horns the macrophage response was tremendously increased. Fluhmann tries to make out a case for treating puerperal sepsis and pelvic inflammations by the administration of the various ovarian and pituitary hormones. It is, however, fairly clear that the work is only preliminary, and it is quite likely that other interpretations may be given to his results.

RECENT WORK IN HÆMATOLOGY

The method adopted throughout the most recent volume [2] of the Practical Medicine series devoted to General Medicine is to abstract the literature of the last 18 months dealing with each subject discussed. The abstracts are clearly presented, but little attempt at criticism is made, nor is a complete picture of any disease or its treatment given. While this method has obvious disadvantages from the point of view of the student, it results in an extremely valuable book of reference for workers in specialised fields, since papers from less well-known journals in many languages are included in the survey. In the section on diseases of the blood, which has acquired much clinical importance in the period under review, Dr. George R. Minot and Dr. W. B. Castle cover the whole field of hæmatology. The papers included deal, as the editors say, "with fundamental physiological questions or techniques of importance in normal and pathological conditions of the blood." The treatment of polycythæmia vera with potassium arsenate is discussed. Cases which have been followed for several years, and unsuccessfully treated with both phenylhydrazine and X rays over the long bones, have shown prompt clinical and hæmatological improvement on administration of potassium arsenate. Remissions have been maintained by continuous treatment, and no untoward effects are recorded. Attention is drawn to the striking clinical parallelism which exists between exophthalmic goitre and chronic lymphatic leukæmia. It is suggested that the beneficial result of treatment with Lugol's iodine in both conditions is due to its action on the sympathetic nervous system. An explanation of the failure of complete gastrectomy in dogs to produce the blood picture of pernicious anæmia is discussed. It has recently been shown by clinical trial that the dog's stomach normally lacks Castle's intrinsic factor. Therefore removal of the stomach produces no deficiency of this factor, and the blood picture of pernicious anæmia, due to such a deficiency in man, does not result. Experiments are described which suggest that human liver acts as a storage for the principle effective in pernicious anæmia. Comparison of the effect of an extract prepared from the liver of a patient with pernicious anæmia who died without treatment, with that of an extract from the liver of a patient dying during a remission, showed the latter to be potent while the former was inactive. The full indices of authors quoted and of subject matter will be appreciated by the research worker in this rapidly growing subject.

PREVENTION OF NERVOUS DISORDER IN CHILDHOOD

Conditions of modern civilisation have made the "nervous child" a figure unfortunately only too familiar. Although it is difficult to estimate with any degree of accuracy the incidence of what has variously been called nervous disorder, nervous instability, or neurosis in any age-group, there is little doubt that it has increased in the last 30 or 40 years, particularly in children of school age. The proceedings of the regular winter conference of educational associations (some sessions of which were reported in The Lancet of Jan. 14th, p. 102) are sufficient testimony to this increase. Many of the operative factors are beyond medical control. The perpetual noise and speed of modern traffic, the increasing number of "one-child" marriages, and the economic difficulties of providing the town child with adequate outdoor playgrounds, are examples. Other environmental factors can be modified by a more enlightened system of education in the home and school. The prevention of nervous disorder in childhood formed a main subject of discussion at the second meeting, held in Geneva last September, of the *Association Internationale de Pédiatrie Préventive.* Whatever part heredity, innate disposition, or so-called organic disease may play in the individual case, it was generally conceded that environment and education will always influence the condition either for good or for bad. There is in fact no such things as a pure endogenous or pure exogenous neurosis. Attention was directed almost exclusively to a consideration of the extrinsic influences brought to bear on the individual child. Prof. F. Hamburger emphasised the importance of an artificial manner of life in the production of neurosis; not only is the child liable to receive inadequate exercise, inadequate exposure to light and air, and an unnatural dietary, but the modern parent is prone to focus a quite unnatural degree of attention on such activities as feeding, excretion, and cleanliness. Fussiness over functions which should normally be largely automatic can only serve to produce a state of unrest in the child's mind, and may result in the very symptoms it is desired to avoid—anorexia, constipation, enuresis. The first essentials of the parents' attitude should be kindness and consistency, with willingness to let the child learn as far as possible from his own experience without unnecessary interference. Several speakers considered the importance of place in family in influencing development; it was pointed out that while a first child may find it intensely wounding to be superseded by a new baby, the psychological trauma is ultimately far less damaging than retaining the position of only child indefinitely. Dr. Heinrich Keller, in a recent study, has similarly observed[1] that the nervous child in Vienna is frequently an only child, and is characterised by an unsocial rather than an antisocial attitude to his contemporaries —lack of desire to make friends from a feeling of superiority. He gives as an example the reply of a 10-year-old boy, the only son of a widow, when asked if he had many friends in the school: "Nein. Ich bin doch ein feines Kind and das sind lauter so Buben!"

[2] General Medicine. Practical Medicine Series, 1932. Edited by George W. Weaver, M.D., Lawrason Brown, M.D., George R. Minot, M.D., William B. Castle, M.D., William D. Stroud, M.D., Ralph C. Brown, M.D. Chicago: The Year Book Publishers. Series 1932. Pp. 837. $3.

In England a subcommittee of the National Council for Mental Hygiene, under the chairmanship of Dr. H. Crichton Miller, recently attempted to state[2] approximately the demand made upon children of various ages, and to indicate the nature of the individual response, the material for the study being obtained from the answers to a questionnaire issued to the heads of 39 schools of all types, with a total attendance of over 10,000 children between the ages of 2 and 18 years. Whilst an investigation of this kind should prove an invaluable preliminary to the removal of any unnecessary stress upon the growing child, it is clear that much of the anxiety and strain of school life is directly traceable to the economic pressure which demands examination qualifications, regardless of the best interests of physical and mental health. Under the present examination system a time factor is introduced and a definite result (which may be of great importance to the child's after-life) is often required by a certain date; the backward child is pushed beyond his capacity, and the precocious child urged to further efforts. Even in schools which pride themselves on scholars taking examinations in their stride, it is pointed out that the length of the stride may be profoundly modified. The two periods which appear to be associated with a maximum of nervous instability and a maximum of punishment—namely, puberty (13–14) and during adolescence (16–17)—are both preceded by a period of working for examinations. Crowding of the time-table also tends to result either in physical education being neglected, or (in schools where games are taken with great seriousness) in rest-periods being quite inadequate. Emphasis is laid on the value and importance of a period of rest in the horizontal position for examination candidates as much as for younger children, though the time devoted to this each day was practically nil in all the time-tables of the 14–18-year-old groups. Indeed, although State infant schools (2–8 years) are the best provided in this respect, in the primary (8–14) group no such provision is made in any of the schools under consideration. For adolescent girls there is a convention which permits intermittent relaxation at school; for boys there is none. The effects of prolonged fatigue upon nervous stability, the report remarks, cannot but be harmful. The report also draws attention to the value of training in accurate movement and performance in inducing nervous stability, and the need not only for the inclusion of handicrafts and gymnastics in the time-table, but for properly trained teachers in charge of these subjects. The report concludes with the suggestion that further research might profitably be directed towards the following problems of school life: size of classes, the number of staff teaching any one child, the hours of sleep and daily rest, recording of height and weight, study of movement as an index of vitality, creative effort, examinations, terminal strains (especially about the eighth week), and punishments.

ANÆSTHESIA IN ANIMALS

ALTHOUGH there are as yet no acknowledged specialists in anæsthesia for veterinary work, yet the knowledge of the science and the technique of administration for animals do not lag behind those employed with human patients. Naturally there are differences in degree and this became particularly evident in Prof. Wright's account of nembutal narcosis in the dog and cat in the course of the discussion at the section of comparative medicine of the Royal Society of Medicine on Jan. 25th. The veterinary surgeon uses nembutal in doses and for a purpose which are not, as Dr. I. W. Magill showed, desirable in the human subject. Nembutal appears to be a good and safe anæsthetic for the lower animals. For human beings its use is mostly restricted to that of an excellent paver of the way for true anæsthesia. One speaker related a case illustrating the extraordinary capacity of dogs to withstand the action of this drug. A dog of 20 lb. in weight received, for lethal purposes, 10 capsules of grs. 1½ nembutal. Next morning the dog was still comfortably alive, although with most reflexes in abeyance, and prussic acid had to be employed to ensure death. The usual dose of nembutal employed for animals appears to be up to gr. ¼ per lb. of body-weight and the results highly satisfactory, no additional anæsthetic being required in many instances. Two papers dealt with epidural analgesia and with anæsthesia for thoracic operations. With regard to the former, opinion was expressed that the method was invaluable for cattle and not sufficiently employed in this country.

Mr. L. O'Shaughnessy, who gave an admirable account of the subject, recommended positive pressure anæsthesia by means of a mask for operations within the chest. He demonstrated the Tigel-Henle apparatus adapted for use in animals and contended that with full narcosis there was no risk of laryngeal spasm, and therefore no occasion for endotracheal anæsthesia. Dr. C. F. Hadfield described a successful anæsthetic given by him for tooth extraction to a 20-year-old Pekinese.

TRENCH FEVER UNDER PEACE CONDITIONS?

A DISEASE of war, springing up mysteriously in 1915 and disappearing as mysteriously in 1919—such is the generally accepted view of trench fever, now considered of historical interest only. Yet no one has adequately explained its complete disappearance after the late war, although its vector, the louse, has survived the conflict. Dr. P.-J. Braslawsky,[1] of Kieff, who reports a case much resembling trench fever, says that during the typhus epidemic of 1920–21 there was a considerable number of cases in the neighbourhood of Kieff of which he personally observed 22. Since then he has seen from 1 to 3 cases yearly, up to 1925, making 32 cases in all. He suggests also that the Wallachian or Moldavian fever described by Dehio in the Russo-Turkish War of 1877–78 was identical with trench fever, and that a series of these cases among the children of a Berlin family described by Apolant in 1904, as well as that of a nurse recorded by Weitz in 1910, were also examples of the disease. Further, a five-day fever, endemic in Galicia for a long time before the war, has been identified with trench fever by Tchirikov and by Francke. Braslawsky therefore thinks it reasonable to suppose that trench or (as he prefers to call it) five-day fever is endemic in certain parts of Eastern Europe, appearing in occasional and often unrecognised cases, and forming a reservoir in the civilian population from which great epidemics may originate in times of war. The only other cases reported since the end of the war appear to be two in Japan recorded by F. Katsurada and J. Yoshino in 1927[2]; but rare diseases are seldom noted unless they are looked for. Although the one recorded by Braslawsky showed four characteristic rises of temperature about every fifth day, it was not typical, since the tenderness of the tibiæ recorded by various observers in proportions of from 50 to 80 per cent. of cases was not present. Unfortunately the only pathological investigation carried out was to exclude the presence of malarial parasites. Presumably the best proof of the continued existence of the disease would be the agglutination of rickettsia bodies from the excreta of lice fed on suspected trench fever patients in the presence of immune serum from animals immunised with infective lice excreta, on the lines of the work of J. C. G. Ledingham.[3] Since the blood of infected persons has been found to be still infective for a period up to 443 days[4] such examination should not prove impossible.

REPORTS ON CHILD GUIDANCE

As the outcome of a White House Conference on Child Health and Protection, called by President Hoover, a subcommittee on psychology and psychiatry was appointed, consisting of eight distinguished psychiatrists, including Prof. Adolf Meyer. Their report, now issued,[5] may be accepted as the considered view of those in the United States who have had most experience of child guidance. Since it is in that country that there has been most activity in this field, and perhaps also most enthusiasm and most optimism, it is of special advantage to get so sober and moderate a review of the subject as is to be found here. Propagandist exaggerations of the need of psychiatric treatment for children, and of the advisability of prompt interference are not accepted, nor the extravagant claims for personnel and time in running such clinics. The place of the general practitioner, the pædiatrician, the social worker, and others who may be concerned is considered temperately. An account of the discussions of the subcommittee is included, and an appendix, with sections on clinics with definite relation to courts, and on special training centres and schools such as the Child Guidance Institute in New York and the Merrill-Palmer school. A valuable section on psychiatric social workers, written by Miss Mildred Scoville of the Commonwealth Fund, provides a clear and vigorous contribution to the difficult question of the relation of these indispensable workers to the psychiatrist and to general social and medical problems of adjustment. This volume is by far the most useful survey of the broader aspects of child psychiatry that has as yet appeared, and should be studied by all who are interested in the development of the work in this country.

The British Child Guidance Council, subsidised by the Commonwealth Fund, has now been established for six years, and has instituted in London, Glasgow, Liverpool, Manchester, and Birmingham clinics for treatment and for training social workers in the delicate task of ascertaining how the child reacts to the environment of home and school, and of altering that environment when necessary. Since the child's environment largely consists of its parents, any attempt to alter it means a systematic education of the parents, and so the child guidance worker is concerned more directly with adults than with children. Dr. William Moodie, at a meeting of the Council held on Jan. 23rd, pointed out that besides instructing its workers the Council undertakes widespread propaganda directed to teachers, doctors, and social workers in other branches. Dr. R. H. Crowley laid great stress on the advice given in the last annual report to child guidance workers: to be sensitive to changing needs and equipped to meet them.

PNEUMATIC MACHINERY AND JOINT LESIONS

EVERY step in industrial progress is apt to bring with it some unforeseen addition to the roll of occupational diseases. Recent reports suggest that machinery driven by compressed air is not guiltless in this respect. Pathological changes in various parts of the body have been described in workers handling pneumatic drills, notably lesions of the bones and joints of the upper limb. The condition has apparently attracted little attention in England, but in Germany especially it is a hazard scheduled under the Workmen's Compensation Act as an industrial disease. This official recognition has been criticised on the ground that the clinical picture is still somewhat vague, and the ætiological relationship with pneumatic drills not established beyond doubt. In a recent paper[1] Meiss sets forth the results of an attempt to end this uncertainty. His conclusions are based on an examination of 107 men employed as riveters or assistants. As a control, 80 manual workers from other fields of labour and 30 non-manual workers were examined. In the first group, 24 men showed changes in and around one or both elbow-joints, and in several cases other joints of the upper limb were also affected. It is suggestive that in the only left-handed worker the condition affected the left elbow only, while in the remainder the right arm was the more markedly involved. In the affected elbow-joint the appearances revealed by X rays resembled those of osteo-arthritis, more especially of the head of the radius. Osteo-arthritis of the elbow-joint was found in five of the larger and one of the smaller control groups, and thus cannot be regarded as necessarily due to the use of pneumatic tools. Of greater diagnostic import, in Meiss's opinion, is ossification in the origin of brachialis anticus, forming a spur upon the front of the humerus just above the elbow. This was found in 20 cases, and in none of the controls with the exception of one man who was found on inquiry to have formerly worked with a pneumatic machine. In some cases ossification was present in other neighbouring muscular attachments—viz., the insertions of biceps, triceps, and brachialis anticus; as Meiss points out, these are the muscles which fix the elbow-joint, and are necessarily exposed to intermittent increase of tension with each vibration of the machine. In several cases there were arthritic manifestations in the carpometacarpal joint of the thumb which Meiss claims to be the first to describe. The thumb is used to grasp the lever controlling the machine, and the joint is thus directly exposed to the vibrations. In one case the right acromio-clavicular joint was affected, in a man who had been accustomed to steady his tool against the right shoulder. Of other conditions ascribed to the use of pneumatic drills, including necrosis of the semilunar bone and arthritis of the sterno-clavicular and shoulder-joints, no examples were found in the present series. The clinical features included pain in the elbow-joint, which is the joint most commonly affected, the pain coming on after ceasing work (the "Ruheschmerz" of German authors), and gradually disappearing when work was resumed; also slight limitation of flexion and extension. There was little or no limitation of pronation and supination; creaking was rarely, slight muscular atrophy frequently, observed. It is emphasised that none of the men had previously complained of the pain, and that there is practically no disability connected with the condition. Where other joints were affected, similar clinical features were noted. Meiss concludes that the evidence points to a probable connexion between joint lesions and the use of pneumatic drills, but that further investigation is required before it can be regarded as proven.

THE HEALTH OF NEW YORK

THE severe economic distress has begun to manifest itself in New York City, according to a report of the Health Commissioner for 1932, in an increase in the number of new cases of tuberculosis. Unless conditions improve this increase in new cases will, without doubt, shortly be reflected by a rise in the death-rate from phthisis, though in 1932 the death-rate from this cause was actually distinctly lower than in the preceding years. Some of this increase in notified cases may rather be due to the admittedly extra zeal with which the department of health has intensified its work of discovering early cases, and to this extent the evidence against economic conditions is not completely convincing. A further consideration is that both the general (crude) death-rate (10·3 per 1000) and the infant mortality-rate (51 per 1000 live births) reached in 1932 their lowest recorded levels. A cause of death that does suggest a distinct increase in prevalence in recent years is diabetes, the increase being especially pronounced among women over 45 years of age. The New York Academy of Medicine has appointed a special committee, in coöperation with the department of health, to consider this problem. Another similar committee, whose report will shortly be available, has been considering the maternal mortality-rate of the city. The rate registered for 1932 was as high as 6 per 1000 live births.

The cost of the health department to New York was, in 1932, 68 cents per head, of which nearly one-third was devoted to child hygiene activities (covering both pre- and post-natal protection), and one-seventh each to the control of infectious diseases and to the supervision of food and drugs. The responsibilities of the department are wide-ranging, as will be seen from the fact that the statistics of motor-car accidents come under its eye. In New York deaths from motor-car accidents reached a peak in 1929, and in the last three years have shown some decline, which the department of health believes can be credited to the greatly increased number of signal lights installed and the extensive campaign of education in street safety inaugurated by the police department in many of the schools of the city.

CARBON MONOXIDE FROM PAINT

ATTENTION was drawn not long ago to the danger of carbon monoxide poisoning from the air of sealed compartments on board ship, and it was shown that the gas was derived from the linseed oil of the paint used in these compartments. Further investigations on this subject have been carried out by S. F. Dudley, F. G. Edmed, and R. C. Frederick.[1] The materials used in the investigation were oxide of iron paint, red lead paint, aluminium paint, bituminous compositions, and two grease paints, one of which contained a small amount of linseed oil. These materials were spread inside petrol tins which were then sealed for varying periods. After one, two, or three months' storage the air from the cans was analysed, and its lethal effects estimated by biological experiments on mice. Linseed oil was again found to be the determining factor in the production of carbon monoxide; the paint dries, oxygen is absorbed, and carbon monoxide is evolved. On board ship it seems that after painting and sealing, absorption of oxygen proceeds to such an extent as to produce an irrespirable atmosphere by the time the compartment is reopened. But at an earlier stage of the process sufficient oxygen for respiration may coexist with a dangerous quantity of carbon monoxide. A man entering such an atmosphere might breathe long enough to absorb a lethal dose of carbon monoxide; this, therefore, is a dangerous period. The quantity of paint, or perhaps rather the surface area exposed, as well as the time during which the compartment has remained sealed, will determine whether the atmosphere will poison those entering with carbon monoxide, or "drown" them from lack of oxygen.

WE regret to announce that Prof. William Phillips Graves, the well-known American gynæcologist, died at Boston on Jan. 25th at the age of 63. Professor of gynæcology at Harvard University and surgeon-in-chief to the Boston Free Hospital for Women, Dr. Graves was the author of a text-book on his subject, and was one of the two recipients of the honorary Fellowship at the recent opening of the new house of the British College of Obstetricians and Gynæcologists. Subsequently he attended the tercentenary dinner of the Society of Apothecaries of London, and conveyed a courteous greeting from the branch of the profession which he represented.

INDEX TO "THE LANCET," VOL. II., 1932

THE Index and Title-page to Vol. II., 1932, which was completed with the issue of Dec. 31st, is now in preparation. A copy will be sent gratis to subscribers on receipt of a post-card addressed to the Manager of THE LANCET, 7, Adam-street, Adelphi, London, W.C.2. Subscribers who have not already indicated their desire to receive Indexes regularly as published should do so now.

SPECIAL ARTICLES

SOME EPIDEMIOLOGICAL FEATURES OF WHOOPING-COUGH

A STATISTICAL INVESTIGATION

BY PERCY STOCKS, M.D. CAMB., D.P.H.

READER IN MEDICAL STATISTICS IN THE UNIVERSITY OF LONDON, AT THE GALTON LABORATORY, UNIVERSITY COLLEGE

(Concluded from p. 216)

PART II

Infection within Houses.—Incubation Period

THE principal modes of infection from child to child which can be studied statistically are (*a*) within the same house, (*b*) from house to house, and (*c*) within the same school.

The distributions of intervals between the onset of successive cases within the same house are analysed in Table VIII. for Battersea and Greenwich. Of the 902 intervals of 0–3 days, more than 800 were pairs of cases recorded as starting at the same time, and it may be assumed that in practically all these instances the two children were simultaneously infected from some source outside the house, and did not infect one another. No doubt this also applies to some of the intervals of 4–6 days, of which there were 87 in Battersea and 72 in Greenwich. It is difficult to decide a priori whether it is more probable that the incubation period could be as short as three or four days, or whether the incubation periods of two children simultaneously infected could differ by this amount, or whether there is an appreciable likelihood that two children living in the same house may be infected from the same outside source on different days. This is virtually settled, however, by the form of the curve in Fig. 1 between 0 and 6 days, for this curve must be the resultant of two component curves which cannot differ much from the hypothetical representation of them as dotted lines, and these suggest that direct infections with intervals as short as two days may be a possibility, and also that almost all intervals of four days or more may be attributed to direct infection of the second child by the first.

TABLE VIII.

Interval between onset of cases.	Frequency of intervals.			Frequency corrected to a range of one day.	Per cent. of successful plate cultures (Madsen).
	Battersea.	Greenwich.	Total.		
0–3 days	521	381	902		75
4–13 "	416	229	645	64·5	57
14–20 "	178	102	280	40·0	
21–27 "	61	58	119	17·0	61

In a large number of instances the interval could be only measured as "one week," an approximate estimate which might mean 6, 7, or 8 days, or even 5 or 9 days. The same difficulty occurs at 14 days. Grouping together 5–9 and 10–17 day intervals in order to escape this difficulty, the Battersea frequencies used in drawing Fig. 1 were as shown in Table IX., and they produce when plotted a perfectly smooth curve. The form of this curve shows that the most frequent interval between successive cases in a house is one week, that the probability of a case occurring at a fortnight's interval is about half as great as this, at three weeks about one-fifth, at a month about one-eighth, and between three and six months about one two-hundredth. It must be concluded that it is possible for the incubation period to be as short even as three days, but it will most probably be a week. The upper limit of the possible incubation period cannot be determined from this data since it is not known how long after onset the infection was conveyed to the second child. Where infection occurs after long intervals the cause is no doubt one of those exacerbations of the more infective catarrhal condition brought about sometimes by superimposed catarrhal infections, which are often noticed in whooping-cough. During such "relapses" to the catarrhal stage it must be presumed that the patient again becomes infective.

Risk of Family Infection

In the last column of Table VIII. are shown the percentages of successful cultures of *Hæmophilus pertussis* reported by Madsen,[9] as obtained by Danish bacteriologists, when plates of a special medium of potato, horse blood, and agar were held at 6 inches from whooping-cough patients whilst coughing. These percentages were based on 914 cases of whooping-cough tested during the first, second, third, fourth, fifth, and sixth weeks of the disease, and more recently Gardner and Leslie [7] have obtained similar results in England. There is an obvious correspondence between the time required for the two measures of infectiousness to decline to a low level indicative of small risk. Although the practice of terminating isolation at the end of six weeks is justifiable on the grounds of greatly diminished risk, the evidence from plate culture experiments gives no grounds for any dogmatic promise that the danger of infection is entirely at an end, since an infective relapse may occur. The Battersea figures show that in fact one case out of every hundred is followed by another in the same house after an interval between six weeks and six months, a small risk but not entirely negligible.

Selecting any child at random who has developed whooping-cough, what is the probability that another child will develop it in the same house (i) within three days, presumably by having been infected from the same source in most cases, (ii) after three days but

TABLE IX

within a month by direct infection, and (iii) after a month but within six months? From the Greenwich data the totals at risk to be followed by a second case which could be reported within the range of the records were respectively 4102, 4070, and 3800 for these intervals, and the respective probabilities were therefore 381/4102, 395/4070, and 101/3800 according to Table VIII. For Battersea the totals at risk during 1925–29 to be followed by a second recorded case were *in each instance* 5574, and the probabilities were therefore 521/5574, 671/5574, and 99/5574. It follows from Table X. that in London about 22 per cent. of all children with whooping-cough will have an associated case within the house within six months, and in about 13 per cent. the infection will presumably be conveyed by the first child to the second. It must be noted that these probabilities are based upon the whole population regardless of whether there are any other children at home liable to be attacked or not. Moreover they are founded on the assumption that reporting was complete, but though this was not the case and the totals are therefore too small,* the *ratios* of second to first cases would not, I think, be seriously affected.

TABLE X

1 to 6 months „ ..	0·018 or 1 in 56	0·027 or 1 in 38

From data given elsewhere [1] it appears that in Battersea the proportions of home contacts excluded from school at ages 5 and 6 who were attacked by whooping-cough after a few days but within six months were respectively 24/195, or 12·3 per cent., and 17/200, or 8·5 per cent., and if these are increased in the ratio 22 : 13 to include the risk of simultaneous infection, they become approximately 21 per cent. at age 5, and 14 per cent. at age 6. Half the mean annual attack rates recorded in children as a whole at ages 5 and 6 were respectively 3·51 and 1·75 per cent. The risk of contracting whooping-cough at ages 5 or 6 was therefore increased six- or eight-fold by the occurrence of a case in the same house. At pre-school ages the relative risk would no doubt be much greater, since the children who were not home contacts would not be exposed to the danger of school infection. The Holborn data showed [8] that of 721 children under 10 who were home contacts and who had not previously had whooping-cough, and who had also escaped any signs of attack during the first three days from onset of the first case, 196 were attacked within six months. Increasing this total in the ratio 22 : 13 to include simultaneous infections, it follows that about 45 per cent. of children under 10 *not previously attacked* would be expected to have whooping-cough *concurrently* with or *within* six months of onset of a case in the house, that is to say, about half would escape by natural or latent immunity.

House-to-house Infection

The distribution of intervals between the onset of whooping-cough in children living in neighbouring houses provides a clue to the importance of house-to-house infection. In Table XI. the result of analysing the intervals between cases in houses in the same street in Greenwich whose numbers differed by 2, 4, 6, 8, is shown for comparison with the distribution of intervals in the same house. Since the numbering of the great majority of streets is alternate, and of a small minority consecutive, houses whose numbers differ by a small even integer would, except in a few instances of end houses in consecutively numbered streets, be on the same side of the street. Where the difference in number was 2, houses would in most instances be next door to each other, but in some instances next door but one; where the difference was 4, houses would be mostly next door but one; but in some instances next but three, and so on. By grouping together houses differing in number by 11, 12, 13 . . . 20, a control group of houses was obtained which would be either on the opposite side of the street, or at least six houses away on the same side.

TABLE XI

The frequencies were then corrected to allow for the limited range of time over which the records were available, thus whilst practically every case during the decade was at risk to be followed by another, one day later, only about 8/10 of them were at risk to be followed by another, one year later, since 2/10 occurred during the last year of the records. The factors by which the actual frequencies had to be divided in order to correct for this are shown at the foot of Table XII. The corrected frequency distributions of intervals between cases when expressed in terms of the corrected frequency of intervals of 1–5 years, a number which could not be in any way affected by infection, will then indicate whether there was a greater risk of infection passing between children in neighbouring houses than between children in houses at a greater distance apart, and also how the risk changes with lapse of time. These are shown in Table XII.

Considering first the relative frequencies of 4–28 day intervals, which give the best index of the risk of house-to-house infection, for houses at a distance in the same street this was four times that expected *if incidence of cases was at random*; for houses whose numbering differed by 4, 6, or 8 it was also four times that expected, but for houses numbered two apart, most of which would be next door pairs, the risk was 9·8 times that expected. This shows that in Greenwich the risk to a child of contracting whooping-cough is more than twice as great if there is a case next door as it is if there is a case in some other house in the street, but is not appreciably greater if there is a case two or three doors away. When there is a case in the same house the risk is about seven times as

---

* I have shown [1] that in Battersea about two-thirds of the actual incidence at all ages is recorded.

TABLE XII

great as when there is a case next door, or 18 times as great as when there is a case in some other house in the street.

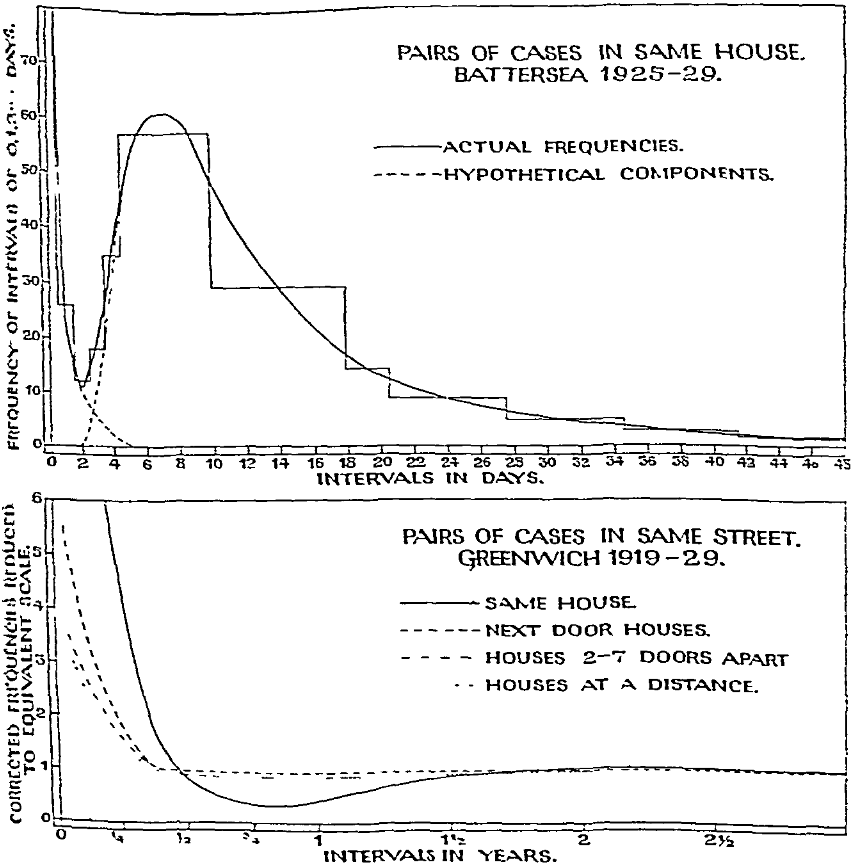
At intervals longer than three months there is no evidence of any appreciably greater risk of infection from next door than from any other house in the street. There is still a risk of infection within the same house, however, as noted above. At 6–12 months' interval there is only half as great a risk that a second child will develop whooping-cough in the same house as that a child will develop it in some other house in the street, whilst at 1–2 years the risk is virtually the same. This forms part of the evidence, given elsewhere,[1] leading to the conclusion that a transient latent immunisation of contacts, protecting them for about a year, occurs. These results are more clearly depicted in the lower part of Fig. 1. As a further check a few houses in different streets were paired at random; with the results shown in Tables XI. and XII. The results do not differ significantly from those for houses at a distance in the same street except that at intervals of 4–28 days the risk is less, suggesting that infection is conveyed between children living in the same street even though they are not living next door.

In the lower portion of Fig. 2 the mean epidemic curve for the nine wards of Battersea in 1928–29, obtained by bringing together the months of maximal incidence in each ward, measuring the time scale forwards and backwards from this and totalling the numbers of cases in each corresponding month on the scale, is compared with the curve for the whole borough, for which the maximal month was December. The amount of dispersion on the time scale is not appreciably diminished by thus comparing the mean epidemic in a single district with that in the borough as a whole—that is to say, although the epidemic wave does not run quite concurrently in the neighbouring districts, it does not move about to the same extent as measles, but is more widely diffused over the whole borough at any given time.

Infection within Schools

In the upper part of Fig. 2 a similar procedure has been followed in the Wandsworth epidemic of 1926–27 in order to arrive at a mean epidemic curve for 21 of the largest schools, and when this curve is compared with that for the borough as a whole, after reducing each to the same total of 1000 cases, there is a notable contrast. The mean school curve rises and falls again much more rapidly than does the curve for the borough as a whole, and reaches a much higher peak. This must indicate that infection is more freely carried from one child to another, and the epidemic comes more quickly to an

FIG. 1



Frequency distributions of intervals between onset of successive cases of whooping-cough.

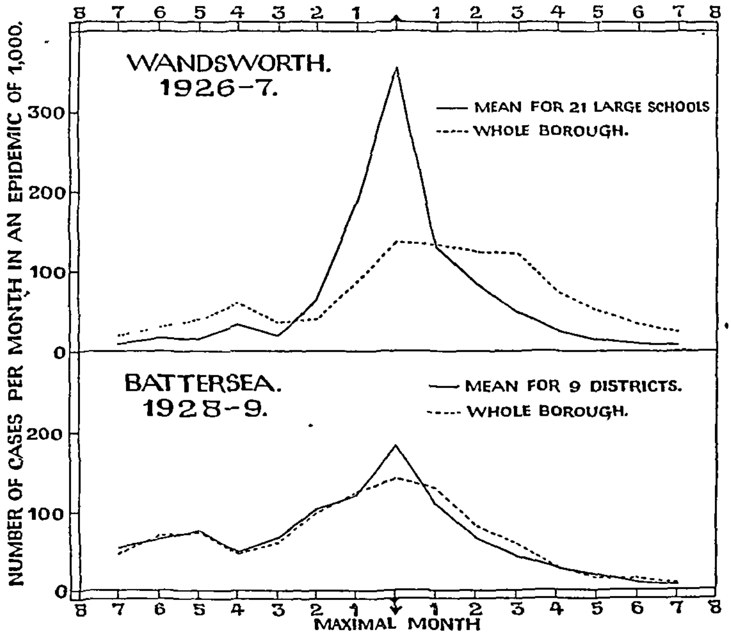
end within a given school population than within the population as a whole.

How is this accounted for? No preventive measures are used except to exclude home contacts. If these were kept at school the epidemic in the school would obviously come to an end just as quickly, perhaps more quickly, and it seems necessary to conclude that the epidemic ends by practically all the susceptible children at school being attacked or rendered immune for the time being. Outside the school, however, the epidemic goes on amongst the younger children almost unchecked, and because they are more scattered it takes a longer time to reach the same end.

Possibility of Control

The question arises whether the practice of excluding from already infected schools home contacts to whooping-cough cases does any good, whether in fact it is not actually harmful. Most of these children spend their time playing with children of pre-school age, and since only an occasional supervision of these children is possible, and the most infectious stage precedes the onset of the whoop, many of them may infect younger children. If every susceptible child attending an infected school is going to either have an attack or develop a latent immunity in any case before the epidemic runs its course, and it is difficult to doubt that in face of the evidence, these children would be better at school until the first sign of catarrh or cough, when they could be immediately sent home and the mothers instructed to keep them indoors. Owing to the much greater danger of whooping-cough to young children it should be our aim, as in measles, to delay as long as possible the attack by seeking to protect the children of pre-school age from infection by school-children. In justification for this it is sufficient to notice that the fatality-rate in Battersea fell from 4 per 100 cases at age 0–1 to 0·2 per 100 at ages 5–10. Street infection has been shown to play some part in the spread of infection, and this might be reduced by the action suggested above.

FIG. 2



Whooping-cough epidemics in London.

Within the home it is also worth while to attempt protection, for although complete isolation may be impossible, a sufficient degree of separation during the most infectious stage may be practicable to so dilute the amount of infection to which the younger children are exposed as to enable them to acquire the necessary temporary latent immunity to secure them from the immediate danger, supposing the theory to be correct. The contention that "they had better get it over whilst they are young" is not a justifiable excuse for saving trouble to parents and school authorities, because in addition to the rapidly diminishing danger to life and to subsequent health with advancing age, there is a reasonable chance, of the order two in five, that if a child escapes immediate attack he or she may escape it altogether. Possibly the use of convalescent serum or parent's blood for home contacts may eventually provide, as in measles, a method of securing the occurrence of a mild attack which will produce a permanent immunity, a more satisfactory result than the mere production of temporary immunity, and in this case isolation within the house would become not only unnecessary but illogical.

Conclusions

(1) The notification records of whooping-cough during the last decade in the metropolitan boroughs of Greenwich, Battersea, Wandsworth, and Holborn combined show an excess of female over male incidence amounting, after correction for changes in sex ratio with age in the populations at risk, to 5 per cent. at ages up to 4 years, increasing to 20 per cent. by the eighth year and 50 per cent. by the tenth year. The excess was considerably greater in Greenwich than Battersea. At ages under 7 there was in Greenwich no excess of girls amongst cases commencing from October to January, but an excess of about 20 per cent. amongst cases arising during the other months. The sex ratio was not significantly different in secondary cases in houses from that in first cases. The age-distribution of whooping-cough incidence is slightly different in the rising phases of epidemics, a somewhat larger proportion of children aged 3 to 6 being attacked.

(2) Children aged 4, 5, and 6 are more liable to infect other children in the same house with whooping-cough than are children of other ages. A study of the distribution of intervals between the onset of cases in the same house leads to the conclusion that the most frequent interval is one week, that the probability of a case occurring with a fortnight's interval is about half as great as this, with three weeks about one-fifth, with a month's interval about one-eighth, and between 3 and 6 months afterwards about one two-hundredth. The incubation period may, it would appear, be as short as three days, but is most likely to be about a week. Infection after six weeks is probably due to an exacerbation of the infective condition brought about by a super-

imposed catarrhal infection. About one case in every hundred is followed by another case in the same house after an interval between six weeks and six months.

(3) The risk of contracting whooping-cough at ages 5 or 6 was increased six- or eight-fold by the occurrence of a case in the same house, and at pre-school ages it would be increased to a greater extent. The risk, at all ages under 10 years, of contracting whooping-cough within a month was, in Greenwich, seven times as great if a case occurred in the same house as if one occurred next door. The risk of contracting whooping-cough within a month was more than twice as great if there was a case next door than if there was a case in some other house in the street, but was not appreciably greater if there was a case two or three doors away. About 45 per cent. of children under 10 who have not had whooping-cough may be expected to contract it concurrently with, or within six months of the onset of, a case in the same house.

(4) Infection between children living in the same street commonly occurs, and the risk of it is greatly enhanced for children living next door to one another. School epidemics tend to come to an end more quickly than in the surrounding district, and it seems probable that practically all the susceptible children at school are either attacked or rendered temporarily immune. The value of excluding from infected schools home contacts to whooping-cough cases is questionable; it would probably be better to keep these children at school until the first sign of catarrh or cough, and then send them home to be kept indoors. It is worth while, if at all practicable, to attempt isolation of a child with whooping-cough from other children within the home during the most infective period, particularly if any of these contacts are under 4 years of age, since this may increase the chance of the remaining children acquiring temporary latent immunity or escaping infection, and postponing the attack until an age when the disease is less dangerous.

(5) The proportions of children known to their parents to have had whooping-cough before entry to school at ages 3, 4, 5, and 6 are greater in those boroughs of London where the population is less dense and better housed. Though this may be partly accounted for by more accurate observation and diagnosis in such areas, it is evident that increased crowding of the population does not in different districts of London result in increased incidence of whooping-cough, but rather the reverse, a phenomenon difficult to account for unless latent immunisation occurs.

Towards the expenses of this research a grant was made by the British Medical Association. I am indebted to Miss Maud Kirby for drawing the diagrams.

MANCHESTER CANCER HOSPITAL.—The Manchester and Salford Hospital Saturday and Convalescent Homes Fund has endowed a bed in the new Cancer Hospital at Manchester at a cost of £1000.

MEDICINE AND THE LAW

Royal Veterinary College: Libel Action

SOME five years ago Capt. Hobbs undertook to raise £20,000 for the Royal Veterinary College at Camden Town, which had fallen on evil days. This sum was thought sufficient to provide a special department for dogs, including a hospital for non-infectious canine patients, an operating theatre, and perhaps a special lecture theatre. Capt. Hobbs was particularly careful to obtain assurances that no part of the money would be used for any vivisectional purpose. Mainly by founding the Tail Waggers' Club and by organising National Dog Week he raised the required sum with the aid of thousands of contributions from dog-lovers. Strange as it may seem, his campaign met with bitter opposition. The College was licensed as a place where experimental work might be done; this fact caused the movement to be suspect. Miss Blanche Watson, propaganda secretary to the local branch of the British Union for the Abolition of Vivisection, wrote a vigorous letter to a Hull newspaper during the second National Dog Week in 1929. She warned dog-owners that by entering their pets as Tail Waggers they were encouraging vivisection. "The long and the short of the business," she wrote, "is to build and maintain the vivisection laboratories at the Royal Veterinary College. National Dog Week and its outcome, the Tail Waggers' Club, are simply masquerading under the cloak of humanitarianism, their real object not being the welfare of the dog but its exploitation." She quoted a statement from a London newspaper that the object of the Club was "the thrusting of torturous experimentation by the arch-exploiter man" upon hapless creatures whose consent was neither asked nor given. She mentioned no names, but Capt. Hobbs (sometimes described as the Tail Wagger-in-Chief) naturally complained that the accusation meant that he was a liar and a fraud. He brought an action against Miss Watson for libel, and he called witnesses who said they thought her letter referred to him and they gathered the impression that he must be a hypocrite. Under cross-examination he agreed that many people felt strongly (as he did himself) about the vivisection of dogs, that the College was registered as a place for vivisection experiments, that some of its professors held licences for that purpose, and that there was a research institute "just across the lawn from the College." This institute, he said, had been entirely excluded from his consideration when he was raising the fund. All these questions to him were directed by Miss Watson's counsel in order to establish her plea that her letter was fair comment on a matter of public interest. Sir Frederick Hobday, principal and dean of the College, explained that it had been arranged that no part of the fund should be used for what was known as vivisection. He described the work of the College, its educational side, and its busy "out-patients' department" to which poor people brought their animals. The research institute was under Government control, with a different governing body from that of the College; the money for the institute came wholly from the Ministry of Agriculture. The defendant in the witness-box declared her abhorrence of vivisection. In 1929 she saw it stated that the National Dog Week was held to endow a chair of research. She understood the statement to mean investigation into human and animal diseases by experimentation on the living animal. To this she was strongly opposed. When she wrote her letter she knew nothing of Capt. Hobbs and had no intention of injuring him. In cross-examination she admitted that she thought the organisers of National Dog Week and the Tail Waggers' Club were deliberately misleading the public as to their intentions. She agreed that she meant to convey that they were getting money from the public by untruths and false pretences. She did not believe that any good had been done by human or animal inoculation. Asked as to the discovery (by means of inoculation) that rats were carriers of bubonic plague, she said it was a quite unnecessary exploitation of the rat because plague could be investigated by other means. In all research work, she said, there was torturous experimentation on living animals. Mr. Justice Branson told the jury that Capt. Hobbs, who was not named in the letter, had no right to complain unless it was understood to apply to him. If the jury thought the letter did imply that he was a hypocrite and had obtained money by the false pretence that he meant to benefit the dogs, whereas his intention was to submit them to vivisection experiments, then the jury might think the letter was defamatory. On the question of damages the judge said that, if the jury thought the plaintiff was entitled to succeed, they would consider the fact that Miss Watson rushed into print without taking the elementary precaution of asking Capt. Hobbs what the real object of the fund was. The jury found for the plaintiff and awarded £500 damages. Judgment was given for this sum with costs.

The limits of fair comment are generous. "Every latitude," once observed Lord Esher, "must be given to opinion and to prejudice." However wrong the opinion expressed may be in point of truth, or however prejudiced the writer, it may still be within the prescribed limits. But the defence of fair comment can be countered if the jury take the view which they took of Miss Watson's letter. She did not, it seems, attempt to justify what she had said. Every vivisection controversy invariably arouses strong feelings. At the beginning of the plaintiff's action, Capt. Hobbs's counsel announced that the trial would involve acute contention between a protagonist of the Tail Waggers' Club and a convinced antivivisectionist; it would therefore be desirable that the jury should not include either persons who held strong views against vivisection or persons whose dogs were members of the Tail Waggers' Club. Two members of the jury were found to belong to the latter class; they left the box and were replaced. The judge confessed that his dog was a Tail Wagger, and, later in the case, when a reference was made to societies formed to combat antivivisection propaganda, he felt obliged to mention that he was himself a subscriber to the Research Defence Society. Nobody objected, however, to his trying the case. Miss Watson's counsel was not concerned to prove that the antivivisectionists were right, but merely to show that the subject was one of public interest about which people might be expected to feel keenly and to express themselves vigorously.

Hospitals' Responsibility for Nurses

A recent Scottish appeal (Reidford *v.* the Lord Provost, Magistrates, and Councillors of Aberdeen) furnishes a valuable statement of the legal responsibility of hospital managers in Scotland in respect of a patient's claim for damages for alleged neglect on the part of a medical practitioner or nurse on the hospital staff. It also shows that the Scots law and the English law reach much the same result though by different principles.

Mr. Reidford, a commercial traveller, was an inmate of the Woodend Hospital, Aberdeen, on two occasions in 1930. He claimed damages against the Aberdeen corporation (as the authority responsible for the hospital) for the alleged carelessness and neglectful treatment which he said he received from the nursing staff. The Aberdeen sheriff court dismissed his action on the grounds that his averments were irrelevant and lacking in specification. This, if a southern lawyer may venture a paraphrase, means that firstly, even if the alleged facts were proved, they would fail to furnish a proper legal basis for a claim, and secondly, the claim failed to supply sufficient particulars—e.g., as to the names of the nurses—to give the hospital authorities a fair chance to meet the allegations. The judgment of the Lord President on the appeal to the Court of Session, well reported in the *Scotsman* of Jan. 28th, indicates that Mr. Reidford complained (*a*) that during his first fortnight in the hospital the nurses omitted to supply him with certain alkali powders at the regular and appropriate intervals as directed by the doctors, and (*b*) that the nurses did not on their own responsibility administer the laxatives which his condition required. Other and later allegations of inadequate food and inattention in the wards were apparently too vague to be considered.

Dealing with the legal position the Lord President first allowed himself the mild criticism that a similar Scottish case (Lavelle's case) which had recently been decided in the House of Lords had been dealt with by their Lordships on the lines of English decisions instead of in accordance with Scottish law. This is a point on which the Scottish courts, administering their own system of law based on that of Rome, are properly sensitive. The Lord President went on to explain the Scots law applicable. There was a complete and infallible test of the liability of hospital managers in the Roman distinction between two kinds of hiring contracts, *locatio operis* and *locatio operarum*. It is a feature of the contract classified as *locatio operis* that the employer is answerable for all defects whether due to his own want of skill and carelessness or that of his servants and subordinates. A *locatio operarum* exists where someone of professional skill is called upon to do and advise what his skill dictates and not what the employer orders: "the person who makes with such a man or woman a *locatio operarum* is not liable for the negligence of the professional person within the department of that professional person's function and skill." It was therefore hopeless to try to make the hospital managers responsible for alleged neglect on the part of the hospital doctors or surgeons whom they permit to exercise their professional functions in the hospital. "The reason is that in the performance of these duties the medical man or the surgeon is making available to the patients his services; he is not acting as the servant of the managers at all; they can neither give him orders nor control him within the limits of the performance of his professional skilled duty." There might be an action against the individual doctor or surgeon; that was another matter. In the Aberdeen case it was clear that the nurses were not, and could not be, acting as the servants of the managers: "they were acting within the department which their professional skill entitled them to act in"; if they were acting expressly on the doctor's orders they were still acting within the area of professional skill and function. "It would be a very dangerous doctrine," concluded the Lord President, "to suggest that the managers of an infirmary were to be supposed to have laid down any rules with regard to any item of the medical treatment of anybody who came into their sick-house. All they undertake is to provide an efficient, well-heated, clean, wholesome sick-house and furniture for the reception of patients, and no doubt to provide the necessary medicines and food." They do not undertake to treat or to cure or to operate upon anybody who is admitted to their institution.

If we compare this judgment (so important at a time when a progressive hospital policy is making treatment available for increased numbers of the public) with the English law, we find much the same result. All members of the staff of an English hospital are personally responsible for damages due to their own negligence. But, if there is a question of suing the authorities responsible for the management of the hospital, there is a simple question of agency and supervision. The hospital is liable for the negligence of persons who are its servants in the sense that their work is subject to the supervision of the committee of management. The hospital is not liable for negligence on the part of physicians or surgeons, paid or honorary, while they are exercising professional skill in respect of which the hospital management has neither the power nor the competence to interfere. The English legal position was made clear in 1905 in Evans *v.* Liverpool Corporation, on a complaint by a patient in the city's fever hospital. It was held that the corporation merely undertook that the patients admitted to its hospital should have competent medical advice and assistance; having appointed a competent and duly qualified medical practitioner the corporation was not liable for his negligence. Thus English law and Scottish law reach the same result, though it may be that the Scottish law gives greater protection to the hospitals in cases where complaint is made against nurses—e.g., in injuries from hot-water bottles. English law would presumably ask whether the alleged negligence arose in work which the nurse was doing as servant of the hospital. The question whether she was in fact acting under the supervision or orders of the medical practitioner in charge of the case has cropped up more often perhaps in patients' claims against the practitioner than in their claims against the hospital. Scottish law would apparently be more ready to say that in all nursing work the nurse's actions would be within the area of professional function and skill and therefore independent of control by the hospital managers. If the Scots law is in fact more favourable, there seems good reason for asking that the English law shall fall into line.

IRELAND

(FROM OUR OWN CORRESPONDENT)

MEDICAL MEN IN THE DÁIL

STUDYING the full list of elections to the Dáil one finds that it contains the names of eight medical men. They are Sir James Craig, Drs. J. J. O'Reilly, J. Lynch, T. F. O'Higgins, R. E. Davitt, F. C. Ward, P. J. O'Dowd, and J. Ryan. Two of these—Drs. Ryan and Ward—held office in the Government. Only one of the medical deputies is coming fresh to the Dáil—namely, Dr. R. E. Davitt. Dr. Davitt is one of the physicians to Jervis-street Hospital, Dublin. Two medical men who have been deputies for several years—Mr. T. Hennessy and Dr. Myles Keogh—have failed to secure election. Both will be missed, for both were prominent figures, and Mr. Hennessy was generally regarded as expressing medical opinion in public affairs. He has an intimate knowledge of medical matters in Ireland, and particularly of the conditions of the public medical services. In his championship of the rights and privileges of the medical profession he never permitted himself to forget that the interest of the public is supreme. He was popular with all parties in the Dáil, and both there and outside his absence will be regretted.

AUSTRALASIA

(FROM OUR OWN CORRESPONDENT)

RECONSTITUTION OF NEW SOUTH WALES MEDICAL BOARD

SOMETHING of a stir has been caused by the Minister for Health, Mr. R. W. B. Weaver, reconstituting the New South Wales Medical Board. Members of the previous Board, who had given many years of honourable service, were communicated with by letter from the Minister, who stated that in very many directions there was a need for an entire rearrangement of the existing conditions. Further, that he had given consideration to the functions of the New South Wales Medical Board and, while deeply appreciative of the work of this honorary body, he considered the time had now arrived for a general reconstruction of the Board. To permit of this he deemed it expedient that the appointments of all members of the existing Board be terminated, and suggested that the members should tender their resignations.

The members of the Board met and communicated with the Minister, stating that they desired to deal with the letter as a Board on Dec. 14th, when they would furnish him with a reply. However, on Dec. 10th a statement appeared in the daily press purporting to emanate from the Minister and indicating that "about seven members of the Medical Board would have to retire on the policy adopted by him, for the reason that they had reached or were over the age of 65 years."

In the morning press of Dec. 14th it was announced "that Mr. Weaver had issued a minute which had been signed by the Government declaring vacant all seats on the Board, and had nominated seven doctors to form the reconstituted Board." A number of letters appeared in the daily press criticising the Minister for his action in this matter, the criticism being levelled not at the personnel of the new Board, but at the manner of dismissal and lack of courtesy to members of the previous Board.

PARIS

(FROM OUR OWN CORRESPONDENT)

AN EXAMINATION SCANDAL

THE suicide of a woman resident medical officer of a Paris hospital has given a tragic turn to a series of incidents which have not been without their lighter side. She was involved in the scandal of the recent examination for resident hospital appointments, and after being summoned, with all the other interns concerned, to give evidence before a representative of the public authorities, she had a nervous breakdown. This examination began last October, between 600 and 700 candidates presenting themselves for about 80 vacancies. In order to eliminate the possibility of the examiners being tempted to favour their own pupils or other candidates towards whom they might feel a kindly partiality, the examination was conducted so as to assure the anonymity of the candidates. Their numbered but unsigned papers were read aloud one after the other to the examiners by a staff of interns, to which the doctor in question belonged. By sandwiching these readers aloud in between the examiner and the examinee, it was hoped that the former would not only be saved from the exhausting task of deciphering much spidery MS., but would also find it easier to pass objective judgment. But unfortunately there seems to have been a widespread belief among the examinees that extra points could be gained if clues to their identity could be furnished in their papers. The whispers about cheating grew into a murmur, and finally into such a general uproar that official action had to be taken by the Assistance Publique. The official inquiry led to the startling discovery that out of 620 candidates, as many as 282, or 45 per cent. of the total, had sent in one or more papers marked in some distinctive fashion. It has therefore been decided to cancel the original examination. A new examination will be held in a month or two, and new examiners will set new questions to the same candidates. If most of the candidates who were successful in the first examination are so again, a cogent answer will be forthcoming to the old objection that such examinations, even when conducted honestly, put candidates at the mercy of too big an element of chance. But this is a very big "if."

THE DOCTOR'S DAY

"Come, tell me how you live," I cried,
"And what it is you do!"

XIII.—AN INDUSTRIAL DOCTOR

BY an "industrial doctor" I mean a doctor who is employed full-time in a factory. In order to give a more intimate picture of the life, I will give a brief description of the factory in which I work and the size of the medical staff. It should be understood that industrial medicine in this country is developing slowly, and that many factories now have clinics, varying in size from a part-time nurse to a complete staff of full-time doctors and nurses.

In the factory where I am employed we make foodstuffs and employ about 5000 workers, of whom rather more than half are men and boys. The medical staff consists of two doctors and three trained nurses, one of whom spends all her time sick-visiting. My clinic reckons to do any work which comes to it, but we do no visiting outside the factory, except (1) to those employees between the ages of 14 and 16 who have no panel doctor, and who ask us to visit them when they are unfit for work; (2) the visiting done by the nurse, which is more in the nature of social than medical work.

The largest proportion of work coming to my department is very similar to that done in a casualty department of a hospital. Much of the work is surgical in type and minor in nature—cuts, bruises, sprains, septic conditions, boils—but there is no limit to the severity of the conditions seen. I keep an emergency bag, and am always ready to do any necessary emergency operation in the factory. Several times I have stood by while a machine was taken to pieces in order to release a worker who was trapped in it and badly injured. Such happenings are, however, emergencies, and we are not fitted to deal with these major injuries throughout their course; we have, therefore, our own ambulance, and we can have any case into hospital within five minutes. On the other hand, moderately severe injuries, such as fractures and lacerated tendons, are not uncommon.

THE MORNING AND ITS VICISSITUDES

By the time I arrive, about 9 A.M., my clerk has a list of all the people who have asked to see us, and we proceed to send for them. We get them in small batches, and this has to be carefully organised, because we do not want to waste the employees' and the firm's time by keeping people waiting unnecessarily; on the other hand, we cannot afford to be kept waiting ourselves, because we may have 100 or 150 patients to see, and we always get through this list before dinner-time. By so doing we leave the afternoon free for redressings, accidents, those people who may be taken ill for medical reasons, and for all the other work which we do, and which I shall describe later. Some of the cases will be surgical, some medical, some new, and some we have seen on the previous day. We treat all medical cases which come to us, provided they are fit enough to stay at work, and we do our own dispensing. We make a small charge to recover the bare cost of the drugs used and, with the exception of such things as vaccines, all other treatment is given free.

So my morning is spent. Perhaps it sounds fairly straightforward and simple; sometimes it is, and sometimes it is the very reverse. The average doctor in practice works more or less to his own time, and is almost completely his own master; in industry, on the other hand, production is always the master, and is ruthless in calling the tune. The work may be done in a constant series of interruptions and inquiries—perhaps about subjects which have only a faint relation to medicine—and one needs much patience and tact. My department has four telephones, and there are times when all of them seem to ring all day long. It can be very exasperating to have to break off in the middle of an examination of a chest to answer a telephone inquiry as to the food value and the metabolism of some article, when the information required is only wanted for advertising purposes. Again, the finest organisation in the world can break down and become chaos simply because several accidents have happened about the same time and have to be treated at once, in spite of the fact that a batch of patients we have just sent for have to be kept waiting. Then the great god of production is held up, and many are the questions which have to be answered. Remember that British industry is fighting for its life, and everything depends on a high output.

The department is kept open during the dinner hour by sending the nurses off in relays; this is done because the workers go to dinner at different times, and because many of them have dinner in our own canteen. The afternoon is taken up by all that other work which has to be done. The jobs are many and varied, and I will describe them briefly.

VOCATIONAL AND OTHER EXAMINATIONS.

All applicants for employment are examined. This does not mean that only absolutely fit workers are taken, but rather that many with physical defects are accepted and their owners placed on the work which they can do. This vocational placing can only be done if the doctor has a very detailed knowledge of the various jobs on which the workers are to be put. A record card is made at the time of the examination, and every visit the employee subsequently makes to the department, with all the necessary information, is entered on that record. Obviously, this vocational selection would rapidly become useless unless every worker passed through the department's hands every time his work was changed. In practice this is done; although the workers do not always have to be re-examined, because it is sometimes possible to tell if they are suitable by reference to their records.

There are, too, many special examinations which have to be made. I keep a list of between 50 and 60 of our higher executives, for whom I do a complete overhaul every 6 or 12 months. The firm believes in prevention, and as these men and women are most important to them, they believe it pays to recognise and treat illness in its earliest stages. This is the whole idea behind the employment of a medical staff; such attention is not given for philanthropic motives, and these purely preventive examinations are illustrations of modern business methods.

Other examinations we do are (1) monthly weighing, questioning, and, if necessary, examination of all cases of tuberculosis which have come back to us after treatment. These cases may be kept on a monthly list for many years, depending on their progress, and are subsequently transferred to a three-monthly list; later, possibly, they are taken off that too. To show the value of this list, I would mention the case of one of my patients who was in a sanatorium in 1913, and from then has been seen periodically, in spite of the fact that he has had no return of positive symptoms. Last year he developed a cough with a positive sputum, and is now back in a sanatorium. (2) After an interval of about six months we re-examine many of the children who have come to us at 14 years of age. Many of them we recognised as having some defects when they came originally, and some of them we find have developed further defects at the end of this period. A large proportion of these children have not reached puberty when they come to the firm, and I think there can be no doubt that their health can be made or marred in the first few years of their industrial life. At the end of six months most of them are well established in their new life, and will continue to do well without fuss, but there are others who need careful watching. (3) Examination of those workers who have some health hazard peculiar to the industry. We have some who are working in fairly high temperatures, where the relative humidity is high, and where there is a good deal of noise. In the case of adult women and young workers of both sexes I regard this as a hazard, and I examine periodically. (4) Some workers are sent to us because they are not doing well at their jobs, and we have to find whether there is any medical reason for the failure. Frequently there is, but it is only arrived at after much searching, and I often feel that a training in psychology would be a great help to the industrial doctor. The reason for any particular patient's failure to adapt to his ordinary life may be deep-lying and far removed from his work, but the result is always seen in his work in the long run, and then becomes vital to him. I am sure that many of us these last few years will have noticed more and more failures of adaptation, with their concomitant nervous symptoms. (5) Insurance examinations for those workers who have been injured and are receiving compensation.

THE DOCTOR AS INDUSTRIAL EXPERT

In addition to these examinations there is work to be done in the factory itself. I am sometimes consulted about the lay-out of new plant, and I am asked what particular type of worker will be needed for a new job—e.g., men, youths, adult women, boys, or girls—and what are the special qualifications necessary. I keep an eye on the ventilation, heating, and lighting of the rooms, and not infrequently I carry out tests, either to satisfy myself or because I have had a complaint about a room. It is essential that one must know how to use a kata-thermometer and a photometer. In addition, I am asked multitudinous questions by the management about every conceivable subject which has, or is thought to have, some medical aspect.

In our quieter moments we try to do some detailed investigations into subjects which are causing us some anxiety—such as sickness rates and the causes of lost time, with particular reference to dysmenorrhœa and functional nervous conditions. But the time available is usually all too short or is interrupted before the study has begun. In industry one has to be prepared to do anything at a moment's notice, and to do it quickly. We once did over 500 vaccinations in two days, in addition to our ordinary work, because there had been a case of small-pox in the factory. We felt that many cases of the disease in a food factory would mean ruin to the firm, and we vaccinated every possible contact. Happily we had no more cases.

During the last ten years I have been with the firm we have had 364,515 patients through my department, giving an average of 36,451 annually. These patients came entirely of their own accord, and it is only in exceptional cases—e.g., infectious or contagious diseases—that any pressure is brought to bear on them.

THE CHOICE OF THIS CAREER

It might be asked whether I would advise industrial medicine as a career. I should have to give a qualified answer. The hours are good; I work from 9 A.M. until about 5.45 P.M. or 6 P.M., and I have no night work to do and I am free on Saturdays and Sundays. I suppose the hours are about the same as those worked in the public health service, but undoubtedly the security is not so great. In industry there seems to be little security for medicine; the science is a new one to them and is not admitted by all industrialists to be a paying proposition. There is therefore no guarantee that any particular firm will continue to employ a doctor, nor is there any guarantee that a firm will continue to be prosperous enough to employ sufficient people to make the services of a full-time doctor necessary. The work itself is very interesting, but to do it well I think a man should be interested in something more than medicine as a science; the number of cases we see of real scientific interest is not great, but one has to deal with many very interesting things, and I personally have acquired some knowledge at least of many interesting people. Industry itself, with its modern methods of efficiency, is an absorbing subject, and is never without its thrills and changes. In a word, I would not advise a doctor to go into industry permanently unless he is prepared to take a risk; for a young man it would not be without interest for a few years, and would certainly help him to get an intimate knowledge of his fellow-men.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

Surg. Comdr. J. F. Ainley is placed on the retd. list at his own request.

ROYAL NAVAL VOLUNTEER RESERVE

Surg. Sub-Lts. E. G. Brewis, P. M. Coats, and G. J. Murray to be Surg. Lts.

Proby. Surg. Sub-Lt. S. I. Ballard to be Surg. Sub-Lt.

ROYAL ARMY MEDICAL CORPS

Lt.-Col. A. T. Frost retires on retd. pay.

Maj. A. B. H. Bridges is placed on retd. pay.

Maj. W. H. S. Burney to be Lt.-Col.

TERRITORIAL ARMY

Capt. T. C. McKenzie to be Maj.

Lt. E. M. R. Frazer to be Capt.

G. M. Goodwille (late Cadet, Edinburgh Univ. Contgt., Sen. Div., O.T.C.) to be Lt.

A. MacDonald (late Cadet, George Watson's Coll. Contgt., Jun. Div., O.T.C.) to be Lt.

INDIAN MEDICAL SERVICE

Capts. D. G. Karandikar and T. P. Rao relinquish their temp. commns.

ROYAL AIR FORCE

Flying Officer D. C. MacGilchrist is promoted to the rank of Flight Lt.

The undermentioned are granted permanent commissions in the ranks stated: Flight Lt. C. A. Rumball and Flying Officers O. M. Fraser and A. M. Weston.

Dental Branch.—The undermentioned Flying Officers are promoted to the rank of Flight Lt.: J. G. Stewart and J. J. Lawson.

HARLOW WOOD ORTHOPÆDIC HOSPITAL.—Although this Nottinghamshire hospital was opened only three years ago an enlargement, which will cost between £12,000 and £13,000, is already necessary. Last week the first sods were cut by the Duchess of Portland, the president, a colliery owner, and a miner who had been unable to walk for ten years but was completely cured in the hospital.

PANEL AND CONTRACT PRACTICE

Certification in Pregnancy and Post-confinement

THERE is considerable misunderstanding on the part of both insurance practitioners and approved societies as to the conditions under which benefit is properly payable during pregnancy and after confinement. The Ministry of Health in Memo. 324/A.I.C. point out that pregnancy is not sufficient in itself to entitle an insured woman to any cash benefit under the National Health Insurance Act. Sickness or disablement benefit can only be paid in respect of a period during which a pregnant woman is incapable of work. A normal, uncomplicated pregnancy would not ordinarily involve incapacity for work, though during its latest stages or in exceptional circumstances a woman might become incapable. A doctor is therefore debarred from giving a medical certificate in order to enable benefit to be claimed unless he is satisfied, as a result of an examination of the woman, that she is incapable of work. After the puerperium (of four weeks) a woman is not entitled to sickness or disablement benefit unless her physical or mental condition is such that she can properly be certified as incapable of work within the meaning of the National Health Insurance Act.

These statements sum up the position clearly, but it is easy to see how difficulties occur. Mrs. A walks into her doctor's surgery, asks for a certificate to go on the panel, stating that she is pregnant. Probably she adds one of the following reasons for her request: "My employers won't have me at work"; "I can't do my work any longer"; "My agent told me to get a certificate from you"; "My friend Mrs. B went on the panel when she was pregnant and I do not see why I should not go on too"; or "Dr. X gave my friend a certificate without any difficulty, and if you don't give me a certificate I shall change my doctor—the agent said I was to get a certificate." This last threat, of course, involves possible loss of confinement fees as well as panel fees, and probably private attendance on the non-insured part of the family—quite a serious consideration to many doctors. How is he to deal with the situation? The first thing to do is to examine the patient and to ascertain (1) the stage of pregnancy; (2) the kind of work; (3) the presence or absence of any physical defects, such as bad varicose veins, piles, œdema of legs, albumin in urine, excessive vomiting. If one of these disabilities are found a certificate can properly be given. If the pregnancy appears to be quite normal, but in its late stages, the kind of work will need special consideration. If before becoming pregnant she was a waitress, the question arises whether she can now act as a waitress without doing herself harm. If the doctor thinks she can, he should refuse a certificate even if she says her employers will not have her back. An exception to this rule is in Class K cases, where a woman marries and leaves off work but continues in benefit for a further year or more; here it becomes necessary to judge her capacity for work when pregnant from the standard of housework. Can she perform without harm ordinary daily household duties? Probably it is only in the very late stages of normal pregnancy that a woman will be unfit to do such work at her own rate, in her own way, though she might be unable to work away from home where she could not rest during the day.

The reason often given for demanding a certificate, that the employer will not have the pregnant woman back at work, is irrelevant to the payment of sickness benefit. If a woman is not incapable of work and her work is not unsuitable to her state, and yet the employer will not have her back, it is advisable for the doctor to write her a private note on a sheet of paper setting out the position. The approved society will then have the onus of deciding, as they do in cases like scabies or impetigo on the face, whether to pay benefit or not. Such cases are not legally incapable of work. On the other hand, the woman who says "I cannot do my work any longer," often has either some additional incapacity or some occupation which involves much stooping or bending, and these patients require careful examination.
